On 18 October 2014, four of us (JAP, AOK, CVG, and DKH) observed a *Crotalus triseriatus* crawling down the limb of a large *Yucca filifera*. The snake was about 2 m above the ground and was followed by an adult male *Sceloporus grammicus*. The lizard was ca. 1.5 m from the snake when initially seen by us and moved to within 1 m from the snake during the observation. The lizard approached the snake in a series of short lunging-like movements separated with short bouts of displays (full-shows with four-leg push-ups and two-leg push-ups without full-shows). The snake continued moving away from the lizard and entered a hollow crevice within the tree while the lizard remained exposed on the limb of the *Y. filifera*. The snake was subsequently captured and confirmed to be large enough (>30 cm total length) to consume an adult *S. grammicus*. Given our estimates of the lizard's approach distance and the length of the snake, the lizard decreased the distance between itself and the snake by approximately 33% but never entered the snake's strike range.

The display behaviors we observed are commonly used in social interactions in *Sceloporus* lizards (e.g., Carpenter 1978. Contrib. Biol. Geol. Milwaukee Public Mus. 18:1–71), but no other lizards were observed in the immediate areas of either interaction reported here. The focal lizard in the first observation was oriented laterally toward the snake while displaying, and both lizards approached the snakes prior to or while displaying. Thus, the lizards decreased the distance between themselves and the snakes while increasing conspicuousness through orientation and displays. The behaviors we observed are similar to those exhibited by *Anolis* lizards during predator-prey interactions with snakes, and the displays described above may serve as pursuit-deterrent signals in *S. grammicus*.

***SCELEPORUS OBERON* (Royal Lesser Minor Lizard). DIET.** This lizard is distributed in the Sierra Madre Oriental in the southeastern mountains of Coahuila and the central southern mountains in Nuevo Leon, Mexico (Köhler and Heimes 2002. Stachelleguane, Offenbach Herpeton. 174 pp.; Lemos-Espinal and Smith 2007. Amphibians and Reptiles of the State of Coahuila, Mexico. CONABIO-UNAM. 550 pp.). To the best of our knowledge there is very little known on the diet of this species. Herein, we report on an individual *Sceloporus oberon* feeding on a centipede, *Orphnaeus brevilabiatus* (Oryidae), an introduced species in Mexico.

On 22 June 2014, at 1125 h, we observed a male *Sceloporus oberon* (SVL = 101 mm; total length = 238 mm; mass = 25.5 g; body temperature = 28.5°C, substrate temperature = 24.5°C; UANL 7406) capturing, subduing, and consuming a centipede, *O. brevilabiatus* (total length = 144.6 mm, mass = 0.4 g). The observation took place in San Isidro Canyon, located in Santiago, Nuevo Leon, Mexico (25.375307°N, 100.311236°W, WGS84; 1600 m elev.). Among lizards of the genus *Sceloporus*, centipedes have been reported to be common prey in the diet of *S. consobrinus* (Lahti and Leach 2009. *In* Jones and Lovich [eds.], Lizards of the American Southwest, pp. 210–212. Rio Nuevo Publishing, Tucson, Arizona), *S. poinsetti* (Webb 2009. *In* Jones and Lovich, *op. cit.*, pp. 246–249); less frequent in *S. torquatus* (Ferria-Ortiz et al. 2011. J. Herpetol. 35:104–112), *S. magister* and *S. undulatus* (Johnson 1966. Am. Midl. Nat. 76:504–509), and *S. siniferus* (Sánchez de la Vega et al. 2014. Herpetol. Rev.45[1]:133–134.). It is important to mention that other species of centipedes occur in this area: *Labrobius major*, *Mexicobius vistanus*, *Nuevobius cavicolens*, *Chomatophilus leonensis*, and *Polycricus nuevus* are potential prey items for lizards. *Orphnaeus brevilabiatus* has recently been collected in the urban area of Puerto Vallarta, Jalisco, Mexico (Capul-Magaña 2009. BIOCYT 2[6]:48–54; Capul-Magaña 2011. Interciencia 36[11]:853–859). Also, our record represents the second occurrence of this centipede in Mexico. Mexico is not included in the known distribution of *O. brevilabiatus* (Minelli [ed.] 2013. Chilobase: A Web Resource for Chilopoda Taxonomy; http://chilobase.bio.unipd.it, accessed 27 June 2014).

We thank Vicente Mata-Silva for reviewing an earlier version of this note.

***SCINCELLA SILVICOLA* (Taylor's Ground Skink). ARBOREALITY.** The nine described species of New World *Scincella* (García-Vázquez et al. 2010. Copeia 2010[3]:373–381; Linkem et al. 2011. Zool. J. Linn. Soc. 163:1217–1243) are typically characterized as terrestrial with an affinity for leaf litter (e.g., Jensen et al. 2008. Amphibians and Reptiles of Georgia. University of Georgia Press, Athens, Georgia. 575 pp.; Canseco-Márquez and Gutiérrez-Mayen 2010. Anfibios y Reptiles del Valle de Tehuacán-Cuicatlán. CONABIO/Fundación para la Reserva de la Biosfera Cuicatlán A. C./Benemérita Unversidad Autónoma de Puebla, México. 302 pp.). The common name for the genus (ground skinks) exemplifies this. However, some published evidence shows that one species, *S. lateralis*, can be scansorial. This species has been reported as "frequently" occupying the overlapping dead fronds of *Sabal palmetto* in Florida at heights of ≤ 45 cm (Lee 1969. Herpetologica 25[1]:70–71), and was observed at night climbing up to 122 cm above ground on a *Nyssa sylvatica* trunk in Virginia (Townsend et al. 2005. Herpetol. Rev. 36[2]:184). Here, we report scansorial behavior and canopy occupancy in another species, *S. silvicola* from México. This observational evidence suggests a much broader ecological niche for this genus.

While conducting a rope-aided herpetofaunal survey of an emergent tree (species unknown) on 12 April 2014 at 1115 h among intact, old-growth rainforest in the Ejido Adolfo Ruiz Cortínez, Municipality of San Andrés Tuxtla, Veracruz (18.53273°N, 95.14403°W, WGS84; 1100 m elev.), we encountered an adult male *S. silvicola* (MZFC 28760). The lizard was discovered inside a 10-cm thick mat of moss and orchids on a horizontal, 20-cm diameter branch ~25 m above ground, in the middle canopy. It was quite active, and initially escaped capture within the complex epiphytic growth.

Additionally, in July 2004 we observed two individuals of *S. silvicola* in the Cuicatlan Valley, Municipality of Santa Maria Texcatitlan, Oaxaca, México, exhibiting scansorial behavior. These animals were observed active at night in a mesquite tree (*Prosopis* sp.) at a height of approximately 2 m above ground.

Our work was approved under SEMARNAT permit #FAUT–0093 issued to A. Nieto-Montes de Oca, and University of Georgia IACUC AUP #A2012 10-004-Y1-A0. We thank Sr. José Charmin for property access. Financial support provided by a University of Georgia Presidential Fellowship.

***SPHENOMORPHUS MULTISQUAMATUS*. REPRODUCTION.** *Sphenomorphus multisquamatus* is endemic to Borneo where it inhabits lowland rain forests and peat swamps (Das 2010. A

Field Guide to the Reptiles of South-East Asia, New Holland Publishers, UK. 376 pp.). There is, to my knowledge, no information on reproduction of *S. multisquamatus*. In this note, I provide information on reproduction of *S. multisquamatus* as part of an ongoing series of studies on reproduction of South-East Asian reptiles.

A sample of 28 *S. multisquamatus* consisting of 9 adult males (mean SVL = 60.4 mm ± 7.3 SD, range = 49–73 mm), 11 adult females (mean SVL = 59.5 mm ± 5.9 SD, range = 8–68 mm) and 8 unsexed subadults (mean SVL = 34.6 mm ± 5.3 SD, range = 25–43 mm) from Sabah and Sarawak were borrowed from the herpetology collection of the Field Museum of Natural History (FMNH), Chicago, Illinois, USA: Sabah (N = 11): Kota Marudu District, FMNH 239896; Ranau District, FMNH 248993, 248995; Sipitang District, FMNH 235168, 235172, 235173, 239899, 239900; Tawu District, FMNH 248994; Tenom District, FMNH 239897, 239898; Sarawak (N = 17): Bintulu District, FMNH 148573, 148577, 148578, 148581, 148585, 148587, 161496, 161499, 161502; Kapit District, FMNH 138536, 145660, 188585; Kota Marudu District, FMNH 239896; Miri District, FMNH 120240, 120242, 120243, 129548. *Sphenomorphus multisquamatus* were collected during the years 1959–1991.

A cut was made in the lower abdominal cavity and the left testis or ovary was removed, embedded in paraffin, cut into 5µm sections and stained with Harris hematoxylin followed by eosin counterstain. Enlarged yolking follicles (> 4 mm) or oviductal eggs were counted. Histology slides were deposited in FMNH.

The only stage noted in the testicular cycle was spermiogenesis in which seminiferous tubules are lined by sperm or clusters of metamorphosing spermatids. Males undergoing spermiogenesis were collected in February (N = 2), June (N = 2), July (N = 2), September (N = 1), November (N = 2). The smallest reproductively active male measured 49 mm SVL (FMNH 239846) and was collected in November.

Four stages were observed in the ovarian cycle (Table 1): 1) quiescent, no yolk deposition; 2) early yolk deposition, basophilic vitellogenic granules in the ooplasm; 3) enlarged follicles > 4 mm; 4) oviductal eggs. There was no evidence that *S. multisquamatus* produces multiple clutches (oviductal eggs and concurrent yolk deposition), although this may reflect my small female sample size. Clutch size (N = 6) was an invariant 3.0. The smallest reproductively active female (FMNH 161499) measured 56 mm, contained three oviductal eggs and was collected in July.

TABLE 1. Monthly stages in the ovarian cycle of 11 adult female *Sphenomorphus multisquamatus* from Sabah and Sarawak; *enlarged follicles (> 4 mm) in one August and one December female were broken and could not be counted.

Month	N	Quiescent	Early yolk deposition	Enlarged follicles > 4 mm	Oviductal eggs
January	2	0	1	0	1
March	1	0	0	1	0
April	1	1	0	0	0
June	1	1	0	0	0
July	2	0	0	0	2
August	2	0	0	2*	0
November	1	0	0	0	1
December	1	0	0	1*	0

Sphenomorphus multisquamatus sub-adults were collected through much of the year: January (N = 1), July (N = 1), August (N = 2), September (N = 1), December (N = 2).

While it is clear *S. multisquamatus* exhibits an extended reproductive cycle, examination of additional monthly samples will be needed to ascertain if reproduction occurs throughout the year as has been reported for other lizards from a Bornean rain forest (Inger and Greenberg 1966. Ecology 47:1007–1021).

I thank Alan Resetar (FMNH) for permission to examine *S. multisquamatus* and L. Lee Grismer for assistance with taxonomy.

***VARANUS PILBARENSIS* (Pilbara Rock Monitor) and *VARANUS GLAUERTI* (Kimberley Rock Monitor). TAIL DISPLAY BEHAVIOR.** Among reptiles, lizards are best known for signaling to conspecifics and to would-be predators (Cooper 2003 *In* Fox et al. [eds.], Lizard Social Behavior, pp. 107–141. Johns Hopkins University Press, Baltimore, Maryland. 438 pp.). Stereotypical displays include head bobbing, pushups, arm waving, foot shaking and tail wagging (Font et al. 2012. J. Comp. Psychol. 126:87–96 and references therein). Some families of lizards are well known for displays (e.g., Agamidae, Dactyloidae), while others are not. Monitor lizards (Varanidae) apparently exhibit limited overt displays (Pianka and King 2004. Varanoid Lizards of the World. Indiana University Press, Bloomington, Indiana. 602 pp.; Sweet 2007. *In* Horn et al. [eds.], Advances in Monitor Research III: Mertensiella 16, pp. 378–402, Reinbach). Herein, we report on observations of apparent tail signaling in *Varanus pilbarensis* and *V. glauerti*.

At 1630 h on 23 February 2014, two of us (SD, BS) noticed a *V. pilbarensis* on a rock ledge on a mesa in the Pilbara region of Western Australia (22.035584°S, 119.413951°E). The adult lizard was about 5 m above us, moving slowly along, tongue flicking, and often stopping to observe us. On four separate occasions, the lizard draped its tail over the rock ledge in a vertically hanging position, and began to wag the tail. The tail wagged in a sinusoidal fashion several cm to each side and slowly at first. After about 3–5 seconds the tail movements would accelerate for a few seconds, culminating in the last few cm of the tail vibrating rapidly. Each tail wag lasted about 10 seconds. During these bouts the lizard was otherwise mainly motionless, although the bouts at times started or ended with "nervous" (but not overly so) movements of the body. After about five minutes the lizard disappeared over the ledge, and despite our climbing and searching we could not relocate it. We were not able to determine the sex of the lizard, but its relatively large size suggested that it was a male. The weather was hot (~35°C) and mostly clear and calm.

One of us (SSS) occasionally observed similar tail wagging displays in *Varanus glauerti* while conducting radio-tracking work with that species (Sweet 1999. Mertensiella 11:317–366; Sweet 2007, *op. cit.*). The behavior occurred mostly in situations where the animal under observation was intent on another subject, but also aware of the observer's presence nearby. During mating season two or even three male *V. glauerti* attended a single female, and the additional male(s) waited 1–3 m away from a mating pair (always in a hollow branch with tails protruding). Twice when these males were closely approached (within about 4 m) they did not leave their sites, but instead engaged in intense tail wagging as described for *V. pilbarensis*. Similar behavior was noted on 4–5 occasions when a *V. glauerti* pursued one or more skinks (*Cryptoblepharus* sp.) through *Dryandra* ferns on narrow rock ledges and came within 2–3 m of an observer. The monitor stopped and

performed 1–3 bouts of strong tail undulations before turning away.

The tail wagging and vibrating we observed appeared to be deliberate signaling. Although lizards often wag their tails when nervous (for example, upon capture varanids will undulate their tail slowly), the *V. pilbarensis* we observed invariably draped its tail over the rock ledge just prior to wagging, but did not drape the tail over the ledge when it was not wagging. During the entire observation we scanned the remaining cliffs for any conspecifics, prey or predators that might have been targets of the signaling, but could find no receiver. In each case of tail wagging in *V. glauerti*, it seemed clear that the observer was the cause and target of the behavior because the behavior occurred upon the observer's approach. The deliberate nature of the displays, and the fact that the lizards could clearly see us, brings us to the tentative conclusion that the tail wagging behaviors we observed were pursuit-deterrent signals (PDS) aimed at us. PDS are used by animals to make predators aware that they have been identified, in order to reduce the probability that the predator will pursue the signaler (Woodland et al. 1980. Am. Nat. 115:748–753; Hasson 1991. Trends Ecol. Evol. 6:325–329).

Sweet (2007, *op. cit.*) reported a different context for tail undulation in *V. tristis*, in which foraging monitors sought out shallow depressions in the forest floor caused by uprooted trees, which were now filled with 10–30 cm of dry leaves. The monitors entered the leaf pack rapidly 2–5 cm below the surface and surged forward 0.5–1 m before emerging and standing high on their forelimbs. Any movement in the leaves elsewhere was pounced on, and skinks (several genera) were actively pursued under the leaves. The standing high posture was usually followed by a bout of rapid tail undulation under the leaves. This was sufficiently energetic to flip some leaves into the air, and often caused concealed skinks to change their positions. There was no indication that this was directed at an observer; rather, it was done to flush prey. Further observations of tail wagging behavior in nature, and perhaps experiments, are needed to determine the frequency of the behavior and its function(s) in *V. pilbarensis*, *V. glauerti*, and in other monitor lizards. Interestingly, the monitor perhaps best equipped to use tail signaling behavior, *V. glebopalma* (distal third of tail bright yellow), never did so in over 1400 field encounters (Sweet 1999, *op. cit.*).

SWEET**, Department of Ecology, Evolution and Marine Biology, University of California, Santa Barbara, Santa Barbara, California 93106-9610, USA (e-mail: sweet@lifesci.ucsb.edu)

***XANTUSIA EXTORRIS* (Durango Night Lizard). FIELD AND PREFERRED BODY TEMPERATURE.** In lizards, body temperature affects virtually all behavioral and physiological traits (Bellure et al. 1996. Ecology 77:1163–1173; Herczeg et al. 2006. Behav. Ecol. Sociobiol. 60:405–414). However, data on preferred body temperature (T_p) is actually quite rare (Sinervo et al. 2010. Science 328:894–899) because measurement in a laboratory thermal gradient under standard conditions is required (Huey 1982. *In* Gans and Pough [eds.], Biology of the Reptilia, Vol. 12, Physiology C, pp. 25–91. Academic Press, New York). The T_p that a lizard voluntarily selects in a laboratory thermal gradient provides a reasonable estimate of what a lizard would attain in the wild with a minimum of associated costs in absence of constraints (biotic and abiotic factors) for thermoregulation (Huey and Slatkin 1976. Q. Rev. Biol. 51:363–384; Pough and Gans 1982. *In* Gans and Pough [eds.], Biology of Reptiles, Vol. 12, Physiology C, pp. 17–23. Academic Press, New York). *Xantusia extorris* is an endemic species of Mexico and has a restricted distribution in northeastern and southwestern Durango and Coahuila, respectively, within the Sierra Madre Oriental physiographic province in the central Chihuahuan Desert (Webb 1965. Am. Mus. Novit. 223:1–16; Bezy et al. 2008. J. Herpetol. 42:680–688; Castañeda-Gaytán et al. 2013. Acta Zool. Mex. [n.s.] 29:240–244). This crepuscular and nocturnal species inhabits desert and arid lands with a ground cover of rocks, fallen yucca plants, fallen branches of Ahuehuete Trees (*Taxodium mucronatum*), and agaves (Webb 1965, *op. cit.*; Gadsden et al. 2006. Bull. Chicago Herpetol. Soc. 41:2–9). There have been several reports detailing thermal ecology in *X. riversiana* and *X. vigilis* (Mautz et al. 1992. Herpetologica 48:271–279; Rabosky et al. 2012. PLoS ONE 7(7):e40866. doi:10.1371/journal.pone.0040866); nevertheless, data on T_p of xantusiids are incomplete (Kaufmann and Bennett 1989. Physiol. Zool. 62:1047–1058; Mautz et al. 1992, *op. cit.*). Both the preferred body temperature in laboratory and body temperature in natural populations have not yet been documented in *X. extorris*. Here, we describe field body temperature and thermal preference under laboratory conditions for this species.

During September and October 2013, we conducted fieldwork in Municipal Ecological Reserve Sierra and Canyon of Jimulco (25.1279°N, 103.2869°W, WGS84; 1640 m elev.), 50 km SE of Torreón, Coahuila, Mexico. Vegetation was dominated by *Yucca* sp. and *Agave lechuguilla*. The data presented are based on 20 adults (> 34 mm SVL) of *X. extorris* captured by hand. Active body temperature (T_b) of each lizard captured was measured using a digital thermometer (Fluke™ model 51-II) with a thermocouple inserted into the cloaca. All lizards were transferred to a laboratory thermal gradient to obtain T_p range. The thermal gradient consisted of a wooden shuttle box of 150 × 100 × 80 cm (length, width, and height) divided into ten tracks with insulation barriers to prevent behavioral influence of adjacent lizards, and filled with 2 cm of sandy soil. The shuttle box was housed in a room with air conditioning at a constant temperature of 20°C. One end of the thermal gradient was heated from below by Nu-Klear (Nu-Klear©, Auckland, New Zealand) thermostatically controlled electric heat pads while the opposite end was cooled using a chamber cooling (by the external side of the shuttle box) apparatus to generate a thermal gradient from 16 to 42°C (Hertz et al. 1993. Am. Nat. 142:796–818). The T_p of lizards were measured every hour from 1740 h and until 1130 h (activity period) using the same digital thermometer used in field. The 25% and 75% quartiles of T_b (T_{b25} and T_{b75}) and T_p (T_{p25} and T_{p75}) ranges were calculated to obtain the lower and upper limit (Van Damme et al. 1990. Oikos 57:61–67; Hertz et al. 1993, *op. cit.*). After laboratory experiments, all lizards were released at their capture sites. We applied a nonparametric Mann-Whitney Rank Sum Test to analyze the differences between T_b and T_p.

There were statistically significant difference between T_b and T_p (U = 959.5, P = 0.01). Mean T_b was 30.2°C (SE = 0.49, range = 24.3–33.2°C; N = 20). Interquartile of 25% and 75% was 29.4°C and 32.0°C, respectively. On the other hand mean of T_p was 28.3°C (SE = 0.27, range = 18.6–35.4°C; N = 149). Interquartile of 25% and 75% was 26.3°C and 30.7°C, respectively.

These results are within the previously reported range of field body temperature for Xantusiidae (Sinervo et al. 2010, *op. cit.*), and suggest that *X. extorris* can be considered a eurythermic

species due to its wide range of T_b and T_p. Future research should evaluate the thermal efficiency by monitoring mean thermal requirements and microhabitat temperatures across its distribution for understanding effects of global warming on this geographically restricted lizard.

SQUAMATA — SNAKES

***ACROCHORDUS ARAFURAE* (Arafura File Snake). FORAGING / PREY CORALLING BEHAVIOR.** Aquatic feeding, including piscivory, occurs in several snake families, and these snakes have predictably evolved adaptations to facilitate feeding on fish. Perhaps the most interesting of these is the "feint" behavior in Tentacled Snakes (*Erpeton tentaculatus*), whereby the snake lies in a "J-shape" and uses its body to startle a fish towards the snake's rapidly approaching mouth (Catania 2009. Proc. Nat. Acad. Sci. USA 106:11183–11187). Below we describe how *Acrochordus arafurae* attempted to prey upon fish in northern Australia.

At ~2230 h on 12 April 2014 two of us (GV and PM) discovered two individual *A. arafurae* in Coomallie Creek, a small perennial system ~70 km south of Darwin, Northern Territory, Australia (13.009798°S, 131.114325°E; WGS 84). The two snakes, which were both approximately 1 m long, were swimming slowly in the creek, which was about 0.3 m deep and clear. One of the snakes became stationary on the bottom (also at 0.3 m depth) and, its head held motionless, began to loop its body counterclockwise around two small (~8 cm) Rainbowfish (*Melanotaenia* sp.) that were also near the bottom. The snake closed the loop by bringing its tail to the left side of its head, and then slowly "tightened" the loop, moving the fish closer to its head. The movement of the body towards the fish was sufficient to move them; they were not touched by the snake. When the fish were within ~5 cm of the snake's head, the snake flicked its tongue, turned its head towards the fish and struck at them. However, the fish eluded capture by swimming rapidly over the snake's body and out of sight. The observation lasted no more than 20 sec.

Because this species feeds almost exclusively on fish (Houston and Shine 1993. J. Anim. Ecol. 62:737–749), our observation likely reflects a novel behavior specifically evolved for capturing fish. It is possible that the snake we observed, like the Tentacled Snake, also used feint behavior in its attempt to capture the fish (the feinting motion is subtle and can only be detected with high-speed film in the laboratory; Catania, *op. cit.*). Although specific behaviors for capturing fish have been observed in other snakes (e.g., Gillingham and Rush 1974. J. Herpetol. 8:384–385; Drummond 1983. Behaviour 86:1–30; Balent and Andreadis 1998. J. Herpetol. 32:575–579; Bilcke et al 2006. Biol. J. Linn. Soc. 88:73–83), we can find no description of corralling behavior in other aquatic snake species. Corralling behavior may have evolved within the acrochordids or within *A. arafurae;* however, it may occur in other aquatic snakes, considering the basal evolutionary position of acrochordids to most other aquatic snakes (Colubroidea) (Lawson et al. 2005. Mol. Phylog. Evol. 37:581–601; Pyron et al. 2013. BMC Evol. Biol. 13:93).

***AGKISTRODON PISCIVORUS* (Cottonmouth). COLD TOLERANCE.** At 1250 h on 18 December 2014, I saw an *Agkistrodon piscivorus* (total length ca. 50 cm) stretched out lengthwise on a levee, a suspected hibernaculum, at the Beech Ridge Unit of the Obion River Wildlife Management Area, Weakley Co., Tennessee, USA. Air temperature was 3.9°C with heavy cloud cover and an approximately 5–10 mph breeze. There had been sleet and rain earlier in the day. Since I did not handle the snake, I could not determine sex or make body measurements. I did not notice any abnormalities or injuries; the snake did not appear emaciated. According to Ernst and Ernst (2003. Snakes of the United States and Canada. Smithsonian Books, Washington D.C. 668 pp.), *A. piscivorus* displays cold tolerance and is active late in the year. I am not aware of any reports of *A. piscivorus* active on the surface at this temperature or colder.

***ALSOPHIS PORTORICENSIS ANEGADAE* (Puerto Rican Racer). DIET / CANNIBALISM.** Snake cannibalism is a rare but well-documented occurrence (e.g., Engeman et al. 1996. The Snake 27:149–152; Göçmen et al. 2008. Curr. Herpetol. 27:1–7; Mociño-Deloya et al. 2009. Anim. Behav. 77:145–150), and for some species, the opportunistic capture and consumption of conspecifics may represent an important and understudied component of the diet (Polis and Meyers 1985. J. Herpetol. 19:99–107). *Alsophis portoricensis* is thought to be a dietary generalist (Henderson and Crother. 1989. *In* C. A. Woods (ed.), Biogeography of

FIG. 1. Adult female *Alsophis portoricensis* juxtaposed against the regurgitated juvenile to show size differentiation.

the West Indies: Past, Present, and Future, pp. 479–517. Sandhill Crane Press, Gainesville, Florida), but the breadth of its diet has received limited attention in the literature. A case of intraspecific predation was described by Perry and Powell (2008. Herpetol. Rev. 39:465) on Guana Island, British Virgin Islands, but as both *A. portoricensis* involved in that report were dead when discovered, it is a possible case of carrion consumption. Here, we report on a second case of cannibalism, also from Guana Island, in which the prey was definitely alive.

On 23 October 2014, at 1230 h, we captured an adult female *A. portoricensis* (SVL = 612 mm; Tail length = 256 mm; 61 g) within the Guana Island hotel complex (18.4793°N, 64.5781°W; WGS84). The snake had a small portion of still-moving tail sticking out of its mouth. Upon capture, the *A. portoricensis* regurgitated a juvenile of the same species (SVL = 181 mm; Tail length = 89 mm; 2 g), appearing by size to be a just-hatched individual (Fig. 1). The ingested juvenile had some perforations from the adult's teeth and initially did not move, but it was not bleeding and slowly recovered. Both snakes were released at the site of capture on the following day, with the juvenile still doing well. Observations of scavenging and cannibalism in *A. portoricensis* (Perry et al. 2007. Herpetol. Rev. 38:203; Perry and Powell 2008. Herpetol. Rev. 39:465) emphasize that these snakes have more diverse diets than sometimes assumed.

Support for this project was provided by the Falconwood Corporation via The Conservation Agency and by Texas Tech University. Photograph provided by Krista Mougey. This is manuscript T-9-1271 of the College of Agricultural Sciences and Natural Resource Management, Texas Tech University.

***AMPHIESMA STOLATA* (Buff Striped Keelback). DIET / SCAVENGING.** *Amphiesma stolata* is known to feed on a variety of prey including frogs, insects, scorpions, fish and lizards (Das 2002. A Photographic Guide to Snakes and Other Reptiles of India. New Holland Publishers Ltd., UK. 144 pp.). Here we report a case of *Amphiesma stolata* preying upon a dead fish (Cyprinidae), at Amlamethi Ghaat, Sundarbans, (22.104056°N, 88.7071°E; datum: Indian Regional Navigation Satellite System [IRNSS]), West Bengal, India. On 5 December 2014, at ca. 1100 h, we observed an *A. stolata* approaching a dead fish and thereafter starting to feed on it. The snake took approximately 10 min to completely swallow the fish headfirst. After this, the snake retreated into adjacent mangrove forest.

FIG. 1 *Amphiesma stolata* scavenging on a dead fish belonging to the family Cyprinidae.

***ANILIOS KIMBERLEYENSIS* (Kimberly Blindsnake). DEFENSIVE BEHAVIOR.** Defenses used by snakes against potential predators include foul-tasting secretions, venoms, hardened scales or shells, large teeth, claws, and tails which may be used as a whip, in addition to camouflage and retreat or "run and hide" behaviors (Greene 1988. *In* Gans and Huey [eds.], Biology of the Reptilia, Vol. 16, Ecology B, pp. 1–152. Alan R. Liss Inc. New York). Although defense strategies are more prominent or visible in some species, other species appear to have little in the way of defense when at risk of capture or predation. The terminal tail spine in some snakes has previously been identified as a morphological feature that may have an antipredator function, although the use and effectiveness of this defense strategy is unknown (Davis 1948. Copeia 1948:208–211; Greene, *op. cit.*). For example, Davis (*op. cit.*) in reference to the use of the tail spine as a defense mechanism by *Farancia abacura* (Red-bellied Mudsnake) stated "when handled would … stab ineffectively with the diminutive spine." Greene (*op. cit.*) noted that this behavior was only known in a few species and suggested it was more widespread in scolecophidians. Greene (*op. cit.*) noted "*Typhlops* thrash, discharge the cloaca, and press a captor with the tail spine." Other than odiferous cloacal excretions no other defensive strategies have been identified in Australian blindsnakes of the genus *Anilios* (Greer 1997. The Biology and Evolution of Australian Snakes. Surrey Beatty & Sons, Chipping Norton, NSW. 358 pp.). This note presents an observation of the use of the terminal tail spine as an apparent defense mechanism by the blindsnake *Anilios kimberleyensis*. *Anilios kimberleyensis* is a small, slender, species found in the Kimberley region of Western Australia and northwest Northern Territory. Similar to most other *Anilios* species, *A. kimberleyensis* possesses a small (1–1.5 mm) conical terminal tail spine.

In April 2012 an adult *A. kimberleyensis* was collected from underneath a sheet of tin at El Questro Wilderness Park in the Kimberley, Western Australia (16.008587°S, 127.977409°E; WGS84). During handling the snake struggled and both its anterior and posterior thirds moved erratically. The tail was slightly coiled and moved continuously back and forth with the terminal tip of the tail and regularly coming into contact with the upper surface of the collector's hand. When the tail spine came into contact with the collector's hand it could be distinguished from contact with the rest of the individual's body; however, it did not pierce the skin or cause any pain. These movements continued for approximately 30 sec. The individual released a small quantity of cloacal fluid with a faint foul-smelling odor when first handled; however, it did not appear as pungent as that produced by other species handled previously. The tail-pricking behavior was briefly observed again when the snake was subsequently examined.

The use of the tail spine as a defense mechanism has not previously been identified for any *Anilios* species and it is unknown at what point it is used and how effective it is against predators. This behavior is likely to be more effective defense against smaller species where the tail spine is more likely to cause discomfort or come into contact with a predator's eye or other sensitive areas, particularly in combination with the odiferous cloacal excretions acting as a deterrent. The terminal tail spine is present on all *Anilios* species other than *A. aspina*, a species

that may have adapted alternative defense strategies. While our observation sheds further light on the behaviour and ecology of Australian blindsnakes, it also identifies knowledge gaps requiring further study.

***APOSTOLEPIS DIMIDIATA*. REPRODUCTION.** *Apostolepis dimidiata* is a small snake (to 630 mm SVL) found in Cerrado and Chaco areas from southeastern Brazil, eastern Paraguay, and northern Argentina (Lema 2001. Cuad. Herpetol. 15:29–43). It belongs to the tribe Elapomorphini, a monophyletic group containing nearly 48 species of poorly-known fossorial snakes widely distributed in South America (Uetz and Hošek [eds.], The Reptile Database, http://www.reptile-database.org; accessed 17 March 2015). Herein, we present the first reproductive information (reproductive mode, clutch size, egg size, and reproductive timing) for *A. dimidiata*.

At 1100 h on 13 December 2009, an adult female *A. dimidiata* (SVL = 319 mm; tail length = 31 mm; and mass = 4.1 g) was found emerging from the soil, after the passage of a bulldozer associated with construction of the Anhanguera Hydroelectric Dam (20.5011°S, 47.8647°W, WGS84; 547 m elev.), situated in the municipality of São Joaquim da Barra, São Paulo state, southeastern Brazil. The animal died later that day, and during the necropsy we found it to contain two extremely elongated eggs (31.0 × 4.8 mm and 31.8 × 5.3 mm), one in each oviduct (Fig. 1). Eggs were surrounded by an opaque, thick, and coriaceous eggshell, indicating oviparity. Dissection of one egg revealed a developing embryo at stage 21 (Zehr 1962. Copeia 1962:322–329), within the range of stage at oviposition in most snakes (Blackburn 1995. J. Theor. Biol. 174:199–216), indicating that egg-laying was near to occur. Reproductive traits reported here (low clutch size, elongated eggs, and timing of gravidity) are similar to other Elapomorphini (Braz et al. 2014. Herpetol. J. 24:49–57).

FIG. 1. Female *Apostolepis dimidiata* collected on 13 December 2009 in São Joaquim da Barra (São Paulo, Brazil) containing two elongated oviductal eggs. The arrow indicates the orientation of the head.

***BOTHROPS DIPORUS* (Southern Pitviper). DIET / OPHIOPHAGY.** Ophiophagy has been reported for at least 10 species in the genus *Bothrops* (*sensu lato*) (Martins et al. 2002. *In* Schuett et al. [eds.], Biology of the Vipers, pp. 307–328. Eagle Mountain Publ., Eagle Mountain, Utah; Marques et al. 2004. Herpetol. Rev. 35:58; Duarte 2008. Herpetol. Rev. 31:45–46). Here we report for the first time a predation event by *Bothrops diporus* upon an adult *Chironius maculoventris*.

At 0235 h, on 24 February 2012, during fieldwork near the Paraguay River in "Estancia La Emilia" (25.94096°S, 57.89160°W; WGS84), northeast of Formosa Province, Argentina, we observed a female *B. diporus* in the process of swallowing an adult *C. maculoventris* (Fig. 1A). The event took place on a dirt road that runs through mixed palm-tree savannah in the Wet Chaco eco-region. The racer had been taken head first and was approximately half swallowed at the time it was found. The head and anterior portion of the *C. maculoventris* were mutilated and exhibited evident external damage and hemorrhaging, particularly in the heart region (Fig. 1 B). Both snakes were collected immediately but only the viper was properly measured (SVL = 73.9 cm), fixed, and deposited at the Universidad Nacional del Nordeste as a voucher specimen (UNNE JRG-197); the size of the racer was estimated (SVL ca. 91 cm) and the specimen later discarded due to the poor quality of the specimen.

Chironius maculoventris is a terrestrial-arboreal, slender, relatively long snake, with largest specimens measuring about

FIG. 1. A) *Bothrops diporus* swallowing an adult *Chironius maculoventris*. B) Predator and prey size comparison.

1.8 m in total length. It is a forest dweller species but can also be found in adjacent open areas (Dixon et al. 1993, Revision of the Neotropical Snake Genus *Chironius* Fitzinger (Serpentes, Colubridae), Monografie XIII, Museo Regionale di Scienze Naturali, Torino, Italy. 279 pp.). As with other vipers of the *Bothrops newiedii* complex, *B. diporus* are mainly forest dwellers and usually considered mammal specialists (Martins et al., *op. cit.*). We were not able to confirm whether this was a predatory event or a case of scavenging upon a road-killed specimen, but *Bothops diporus* is very common at this location and the road has almost no traffic at all. Thus, it seems plausible that this arboreal racer had been predated when crossing the road to move between forest patches.

We wish to acknowledge the personnel of Estancia La Emilia (MSU Río Porá SA) and to José Augusto Ruíz García from the Universidad Nacional del Nordeste for properly identifying and measuring the snakes.

***BOTHROPS ERYTHROMELAS* (Jararaca Dry). ENDOPARASITE.** Snakes are parasitized by a wide variety of invertebrates (Silva et al. 2001. Rev. Bras. Par. Vet. 10:91–93). The endoparasite *Cephalobaena tetrapoda* (Heymones, 1922) is a species of Pentastomida that infects the respiratory tract of snakes (Almeida et al. 2007. Braz. J. Biol. 67:759–763; Almeida et al. 2008. Braz. J. Biol. 68:193–197). Only four species of snakes have been recorded as hosts for these species of Pentastomida: *Bothrops (Lachesis) alternatus* (Viperidae), *Lygophis lineatus* (Colubridae), *Oxybelis aeneus* (Colubridae), and *Phylodrias nattereri* (Colubridae) (Almeida et al. 2006. Braz. J. Biol. 66:559–564; Almeida et al. 2008, *op. cit.*). All of these species of snakes feed on small vertebrates, mainly lizards and frogs (Mesquita et al. 2013. Pap. Avul. Zool. [São Paulo] 53:99–113), which therefore should represent the intermediate hosts for *C. tetrapoda* (Almeida et al. 2006, *op. cit.*; Almeida et al. 2008, *op. cit.*). The genus *Bothrops*, belonging to the subfamily Crotalinae, has a wide distribution in South America, occurring from Mexico to Argentina (Valdujo et al. 2002. J. Herpetol. 36:169–176). In November 2012 a male *B. erythromelas* (SVL = 362 mm; Tail Length = 58 mm; 17 g) was captured on Sítio Pedra Preta – municipality of Farias Brito (39.533194°W, 06.783278°S, WGS84; 309 m elev.), Ceará, northeastern Brazil. The specimen was euthanized and deposited in Herpetological collection of Universidade Regional do Cariri (URCA H 4996). The respiratory tract of the snake was removed for analysis of parasites under a stereoscopic microscope. A specimen of *C. tetrapoda* was identified. This represents the first record of *B. erythromelas* as definitive host for *C. tetrapoda* (collection among the Regional University of Cariri-URCA P 389). *Cephalobaena tetrapoda* causes lesions in the lung tissue (Almeida et al. 2008, *op. cit.*), obstruction in the trachea (Paré 2008. J. Exo Pisto Med. 17:285–294), reduced fertility, and increased mortality, and may act to control populations of infected snakes (Riley 1986. Adv. Parasitol. 25:45–128; Pence and Selcer 1988. Copeia 1988[3]:565–572).

Scholarships were provided by CAPES (D. A. Teles and A. A. M. Teixeira), FUNCAP (J. A. Araujo-Filho), and CNPq (W. O. Almeida).

***CROTALUS HORRIDUS* (Timber Rattlesnake). COLORATION, PATTERN, EXOPHTHALMIA, AND ENOPHTHALMIA.** On 24 July 1885, an adult *Crotalus horridus* variously described as having skin "white as milk" and "white as paper" was discovered by John Sheridan near the rural hamlet of Ladow's Mills, in the vicinity of Corydon, McKean Co., Pennsylvania, USA (Anonymous 1885. The New York Times, July 31). This represents the earliest known written description of an abnormally colored *C. horridus*. The interest of the general public in such an animal is attested to by the fact that, within a week, an account of the discovery was published in one of the country's largest metropolitan newspapers.

Since that time, 10–12 (two are likely the same specimen) *C. horridus* characterized as exhibiting some lack of pigmentation (albino, amelanistic, or xanthic) have been reported in the literature (Hensley 1959. Publ. Mus., Michigan State Univ. Biol. Ser. 1:133–159; Dyrkacz 1981. SSAR Herpetol. Circ. No. 11. 31 pp.; Hudson and Carl 1985. Herpetol. Rev. 16:28–29) and more recently on internet websites. Most of these specimens exhibited faint, but discernable, normal dorsal banding patterns and tended to have a yellow or tan skin coloration. Two of these snakes were also collected from Pennsylvania. E. Cheuvront and S. Harwig found a "xanthic" *C. horridus* with "brassy iris" in 1954 (Hensley, *op. cit.*; S. Harwig, pers. comm.). Although preserved for over 60 years, this specimen (CMNH, CM 34696) still shows the vestiges of a normal pattern (H. K. Reinert, pers. obs.). The second specimen, collected in 1962, exhibited a reduction in pigmentation, but retained a clearly discernable pattern, black tail, and normal colored iris (Grube 1963. Turtox News 41:70).

On 28 May 2001, a male *C. horridus* with aberrant coloration was collected in western Pennsylvania. This snake was 34 cm (total length) with a single rattle segment (terminal button) indicating that it had been born the previous fall. The skin of the snake was slightly translucent and appeared light pink or white in coloration. The snake was patternless with the exception of two very small black spots on the dorsum (Fig. 1A). On 25 August 2002, in the same general vicinity, a litter of newborn *C. horridus* was observed that included another anomalous individual along with 6–7 normal patterned siblings. This snake, a 32 cm female, was also white or light pink with slightly translucent skin. It too was patternless with the exception of a small (<1 cm diameter) dark patch on the dorsum (Fig. 1B).

At the time of capture, both snakes displayed bilateral exophthalmia, white irises, abnormally large, round pupils that were non-responsive to light, and pink tongues (Fig. 2A, B). H. Bernard Bechtel examined photographs of the male snake and concluded that it displayed a form of leucism (H. B. Bechtel, pers. comm.) similar to that exhibited by *Pantherophis obsoletus* [*Elaphe obsoleta lindheimeri*] (Bechtel and Bechtel 1985. J. Hered. 76:7–11). Reportedly, several leucistic specimens of *P. obsoletus* also displayed exophthalmia (Bechtel and Bechtel, *op. cit.*).

Both rattlesnakes have been maintained in captivity. The male has grown to 106 cm and the female to 92 cm in total length. Over time, the skin of both snakes has become less translucent and whiter in appearance, likely due to thickening of the epidermis. The amount of skin pigmentation has also increased greatly in both snakes. However, no semblance of normal pattern has emerged. Instead, both snakes have become increasingly spotted with black, brown, orange, and pale yellow in a seemingly random

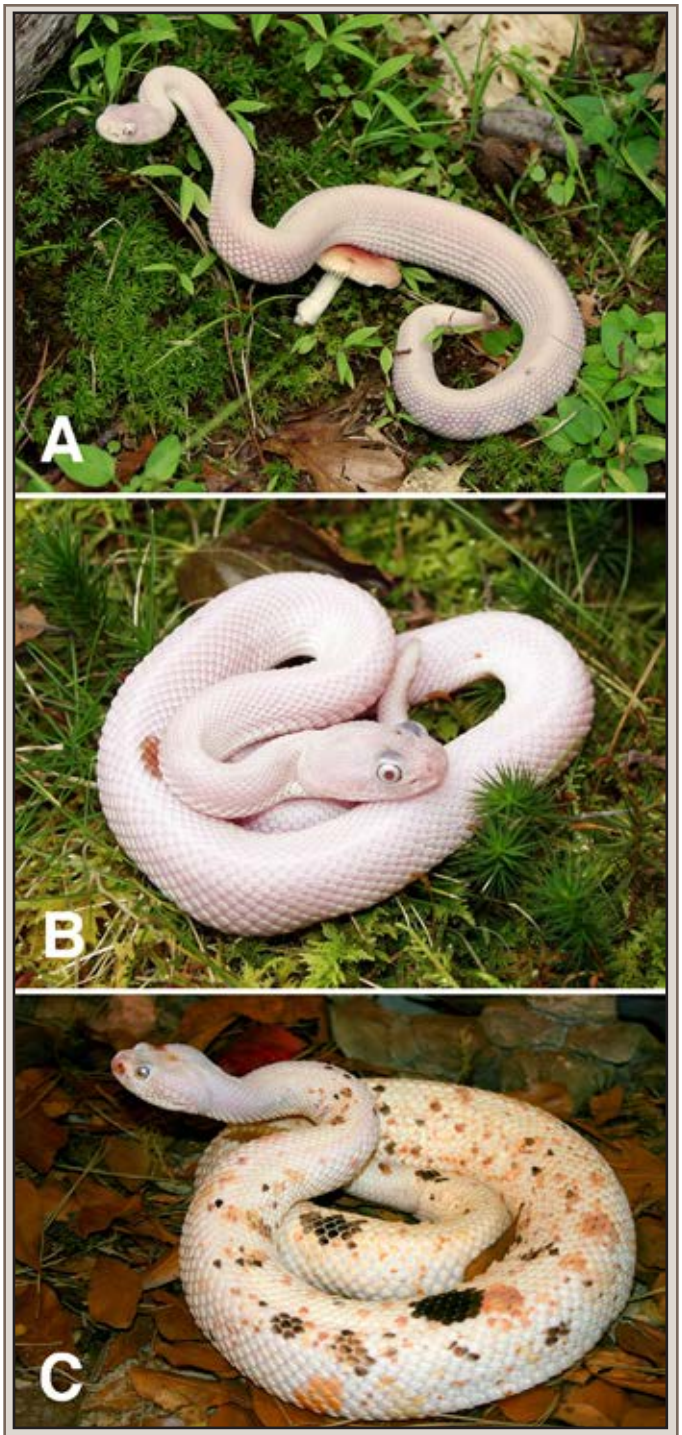

FIG. 1. General appearance of the male *Crotalus horridus* when captured in 2001 (A), the female when captured in 2002 (B), and the female as an adult in 2014 (C).

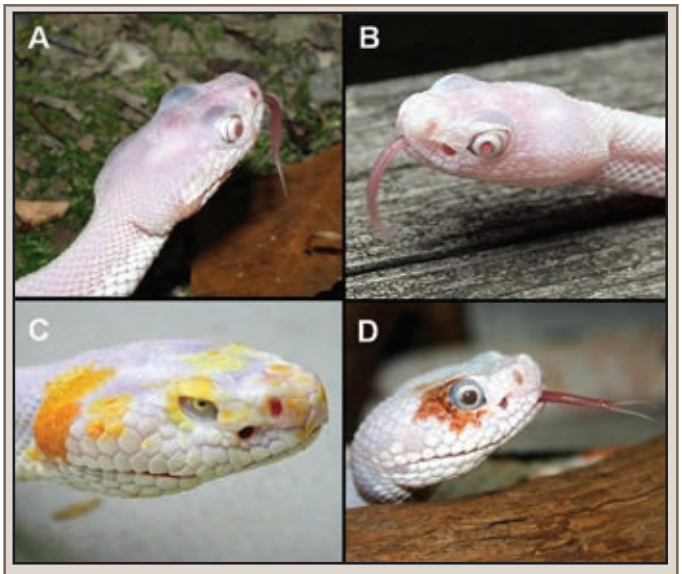

FIG. 2. Exophthalmia in the male *Crotalus horridus* in 2001 (A) and the female in 2002 (B) when captured. Enophthalmia in the adult male (C) and exophthalmia in the adult female (D) in 2014. Rounded pupils, white irises, and pink tongue are also evident.

manner (Fig. 1C). It is unlikely that leucism correctly describes the anomaly displayed by these snakes because chromatophores typically do not develop in the epidermis of leucistic organisms (Bechtel 1995. Reptile and Amphibian Variants: Colors, Patterns, and Scales. Krieger Publishing, Malabar, Florida. 206 pp.).

The eyes of the male did not continue to grow in proportion to the head and body. They remained small and have become enophthalmic (Fig. 2C). The eyes of the female, however, have continued to grow and remain exophthalmic (Fig. 2D). Both snakes have severely impaired vision and do not appear to visually track movements. However, both are responsive to warm prey, strike accurately, and eat regularly. The male has become progressively less flexible and mobile. He moves laboriously, typically using rectilinear locomotion and cannot balance on a snake stick. He also does not coil, but always lays out-stretched suggesting spinal ankylosis. He has not suffered any known spinal injury. The female, however, shows normal movement ability and regularly coils in resting and foraging postures typical for this species (Reinert et al. 2011. Copeia 2011:430–442).

The two snakes described in this report appear to be the first wild-caught *C. horridus* to exhibit such unique combinations of color, pattern, and ocular anomalies. Both were captured as neonates, and considering that their births were separated by two years, it is possible that they have shared parentage (Martin 1993. J. Herpetol. 27:133–143). Although the male snake apparently overwintered successfully, their lack of both cryptic coloration and eyesight makes it unlikely that either snake would have survived long under natural conditions.

Both specimens are currently maintained at Clyde Peeling's Reptiland, Allenwood, Pennsylvania. Gian Rocco, James Chestney, Stephen Rogers (CMNH), and Steve Harwig provided field assistance and information. Robert T. Zappalorti photographed adult snakes. We thank Christopher Urban (Pennsylvania Fish and Boat Commission) for required collecting and holding permits.

ALAN HOLLINGSWORTH and **HOWARD K. REINERT**, Department of Biology, The College of New Jersey, P.O. Box 7718, Ewing, New Jersey 08628-0718, USA (e-mail: hreinert@tcnj.edu).

***CROTALUS OREGANUS* (Northern Pacific Rattlesnake). SCAVENGING.** Scavenging of carrion has been documented in numerous species of snakes (DeVault and Krochmal 2002. Herpetologica 58:429–436) including pitvipers of the genus *Crotalus* (Dornburg and Weaver 2009. Northwest. Nat. 90:55–57). Dornburg and Weaver (*op. cit.*) observed a juvenile *C. oreganus* attempt to remove a road-killed *Peromyscus maniculatus* (Deer Mouse) from a road surface in Washington State, USA. Herein, we provide an

FIG. 1. An adult *Crotalus oreganus* consuming a *Tamias quadrimaculatus* (Long-eared Chipmunk) as carrion in Amador Co., California, USA.

additional observation of *C. oreganus* scavenging and consuming road-killed prey.

At 1743 h on 21 August 2013, while driving along Panther Creek Road (38.507294°N, 120.358098°W; NAD 83) in Amador Co., California, USA, an adult *C. oreganus* (ca. 85 cm total length) was observed scavenging a dead *Tamias quadrimaculatus* (Long-eared Chipmunk) (Fig. 1). Following our initial observation, the rattlesnake retreated off the road into the vegetated shoulder, with the chipmunk in its mouth and always faced us during this movement. Once in the vegetated shoulder, the rattlesnake began swallowing the chipmunk head-first and we departed after it was approximately 75% consumed. The chipmunk appeared flattened and crushed and was covered with approximately 15–20 yellowjacket wasps (*Vespula* sp.), suggesting that it died from being crushed by a car, rather than from envenomation by a rattlesnake.

We thank Harry W. Greene who encouraged us to publish this observation and reviewed this note.

WISEMAN, Garcia and Associates, 2601 Mission Street, Suite 600, San Francisco, California 94110, USA (e-mail: kwiseman@garciaandassociates.com); Department of Herpetology, California Academy of Sciences, 55 Music Concourse Drive, Golden Gate Park, San Francisco, California 94118, USA; **BEN J. KRYZER**, 715 Chapel Lane, Tahoe City, California 96145, USA.

***CROTALUS WILLARDI* (Ridge-nosed Rattlesnake). PREGNANCY / MATERNAL CARE / MALE ACTIVITY.** The phenomenon of post-partum maternal care has been described in North American pitvipers, which includes rattlesnakes (Greene et al. 2002. *In* Schuett et al. [eds.], Biology of the Vipers, pp. 179–206, Eagle Mountain Publishing, Eagle Mountain, Utah; Hoss and Clark 2014. Ethology 120:933–941). Here, we describe several cases of pregnancy and maternal care in *Crotalus willardi* from Arizona at a single location on a single day. Additionally, we report on male activity associated with pregnant and post-partum females.

On 10 August 2008, at 0950 h, two of us (BPO, BTL) arrived at a small hillside (1646 m elev.) in the Patagonia Mountains (Arizona, Santa Cruz Co., USA; 31.416°N, 110.733°W, Conus 27). Weather conditions were mild (26°C) and the sky was partly cloudy. The ground was damp and there appeared to have been recent rainfall. At 1010 h, a large, pregnant *C. willardi* (female-1) was observed basking along the edge of dense bunch grass. At 1025 h, about 30 m from the first female, a second pregnant *C. willardi* (female-2) was observed retreating into loose rock which formed a gradual slope. At 1040 h, about 15 m downhill from first two females, a single exposed (coiled) adult male *C. willardi* (male-1) was observed. At 1105 h, a third female *C. willardi* (female-3) was located on the hillside that was post-partum and was with six neonates. Since no other female was with her, we assumed that the neonates associated with female-3 were her genetic progeny (see Parker et al. 2013. Herpetol. Rev. 43:658–659). The offspring were in close contact with female-3; when we approached, she retreated deeper into the rock shelter and all the neonates followed her (Fig. 1A). Most of the neonates had "blue" eyes, indicating they had not yet undergone their first shed (Greene et al., *op. cit.*). A fourth female (female-4) *C. willardi* was located about 8 m from female-3 and also appeared to be pregnant. She quickly retreated into rocks when approached.

PHOTOS BY BRENDAN P. O'CONNOR

FIG. 1. Maternal care and male behavior of *Crotalus willardi*. (A) Neonates of female-3. Female-3 was present beneath neonates. (B) Male-2 (yellow arrow) that was found in close association with female-2. Note distended body of female, which is indicative of pregnancy. (C) Neonates positioned on top of female-3.

At 1200 h, we returned to check on females 1 and 2, and both were found at their original locations. However, a young, adult male *C. willardi* (male-2) was located coiled next to female-2 (Fig. 1B). The male performed some light courtship acts (head-jerking, tongue-flicking) on female-2. At 1323 h, female-3 and her neonates had shifted toward the surface beneath a palm-sized rock; most of the neonates were coiled on top of female (Fig. 1C).

On several occasions, Greene et al. (*op. cit.*, p. 190) found femae *C. willardi* with their litters in the Huachuca Mountains. Tanner (1985. Great Basin Nat. 45:615–676) reported a female *C. w. silus* with a litter from western Chihuahua, Mexico. Our observations of male *C. willardi* occurring with or nearby pregnant or post-partum females are intriguing. This type of male behavior has been witnessed by us (BPO, BTL) on several other occasions in this species and under similar conditions. Male "visitation behavior" (of pregnant and postpartum female) has been documented in other rattlesnake species (see Holycross and Fawcett 2002. Amer. Midl. Nat. 148:181–184). Genotyping studies are planned for *C. willardi* to better interpret the social behavior of males visiting both pregnant and post-partum females with neonates.

Ryan Sawby kindly prepared the figure.

***DRYMARCHON COUPERI* (Eastern Indigo Snake). HISTORICAL RELATIVE ABUNDANCE.** *Drymarchon couperi* is one of North America's largest native snake species and has the largest reported home range size of any native snake on the continent (Breininger et al. 2011. J. Herpetol. 45:484–490). *Drymarchon couperi* uses a diverse array of natural and human-altered upland and wetland habitats that varies seasonally, by sex, and by body size (Breininger et al., *op. cit.*). *Drymarchon couperi* is diurnal and is known to consume at least 47 species, individually dominated in descending order by snakes, anurans, rodents, and turtles or their eggs (Stevenson et al. 2010. Southeast. Nat. 9:1–18). As large, wide-ranging, terrestrial apex predators that must feed often to meet energy requirements (Stevenson et al. 2010, *op. cit.*), *D. couperi* may substantially affect the composition and abundance of its prey base, particularly other snake species (Steen et al. 2014. Herpetologica 70:69–76). Here I report that in the mid-1970s *D. couperi* was the most commonly encountered snake species at two coastal sites in Lower Tampa Bay, Florida, USA.

As an environmental consultant, I and others surveyed amphibians and reptiles (diurnal visual encounter surveys, turning surface objects, etc.) and small mammals (live traps) at least monthly (April 1974 through March 1975) at two proposed electric power plant sites owned by Tampa Electric Company. The two sites (Big Bend: 27.7938°N, 82.3990°W, WGS 84; Beacon Key: 27.6654°N, 82.5171°W) were each about 607 ha and located 18.4 km apart. Habitats were similar, consisting of coastal strand and mangroves along Lower Tampa Bay, and transitioning inland into salt pans and black rush marshes, hardwood hammocks, flatwoods, oldfields, and active vegetable fields intermixed with drainage ditches, freshwater marshes, and small ponds. U.S. Hwy 41 bordered both sites on the east and neither contained any internal paved roads. Gopher Tortoises (*Gopherus polyphemus*) were present, but uncommon, at both locations.

During the study a total of 18 snakes of 10 species were collected: 6 *D. couperi*, 3 *Coluber constrictor*, 2 *Crotalus adamanteus*, 2 *Nerodia fasciata*, and 1 specimen each of *Lampropeltis elapsoides*, *Pantherophis alleghaniensis*, *P. guttatus*, *Thamnophis sauritus*, and *Diadophis punctatus*. The six *D. couperi* were 1.03 m, 1.40 m, 1.94 m, 1.98 m, 2.00 m, and 2.11 m in total length, and included three of each sex. Months of capture were November (1), December (2), January (1), and June (2). One snake contained a *Sigmodon hispidus* (Cotton Rat), the most commonly trapped small mammal. *Drymarchon couperi* were observed in coastal strand, hardwood hammock, flatwoods, oldfield, and on a dirt road between cucumber fields, suggesting wide use of available habitats.

Although the sample sizes are small, to my knowledge this is the first reported example of the seemingly numerical dominance of *D. couperi* in a snake faunal assemblage. In 50+ years of snake hunting in Florida, I have no comparable data. However, during this same historic time period, Paul Moler (pers. comm.) received several reports that *D. couperi* were exceedingly common along canal banks in citrus groves near Ft. Pierce, St. Lucie Co., Florida, and Terry Whitaker (pers. comm.) captured more *D. couperi* than any other snake species along canal banks in sugar cane fields near Pahokee, Palm Beach Co., Florida. It is possible that *D. couperi* only reached such high abundance in human-altered habitats, or that their large body size and active diurnal hunting behavior makes them the most detectable snake in such habitats. Given the potentially significant predatory effects of *D. couperi*, these findings have implications for evaluating prey populations in the current, fragmented range of indigo snakes and for the reintroduction of this species into Alabama and North Florida.

***DRYMOBIUS MARGARITIFERUS* (Speckled Racer). DIET.** The diet of *Drymobius margaritiferus* is known to consist of anurans and their eggs, lizards, reptile eggs, and small mammals (Pérez-Higareda 2007. Serpientes de la Región de los Tuxtlas, Veracruz, México. Guía de Identificación Ilustrada. UNAM, México. 189 pp.; García 1994. Guía de Campo de los Reptiles y Anfibios de la Costa de Jalisco, México. Fun. Ecol. de Cui. AC, IBUNAM, México. 184 pp.), but few anurans have been identified to species. Here we report the first account of a *D. margaritiferus* consuming

FIG. 1. Two *Craugastor occidentalis* recently preyed upon by a *Drymobius margaritiferus*; all of them road-killed shortly thereafter.

Craugastor occidentalis (Taylor's Barking Frog) from the municipality of Cuauhtemoc, Colima, Mexico.

On 16 June 2014, a *D. margaritiferus* was found dead on the Cuauhtemoc–Buenavista freeway in the municipality of Cuauhtemoc, Colima, Mexico (19.291019°N, 103.594888°W, WGS84; elev. 794 m). The snake was still moving and most likely had been hit by a car. Two dead *C. occidentalis* were found right next to the exposed stomach of the snake (Fig. 1). The frogs had different degrees of digestion but they were still complete enough to be identified. The freeway where the snake was found is surrounded by patches of tropical deciduous forest and sugar cane and rice fields.

***ERYX JACULUS* (Javelin Sand Boa). REPRODUCTION.** *Eryx jaculus* is widely distributed and is known from eastern Europe, Greece, Turkey, Transcaucasia, the Middle East and Africa north of the Sahara (McDiarmid et al. 1999. Snake Species of the World, A Taxonomic and Geographic Reference. Vol. 1, The Herpetologists' League, Washington, D.C. 511 pp.). It is ovoviviparous (Disi et al. 2001. Amphibians and Reptiles of the Hashemite Kingdom of Jordan, An Atlas and Field Guide. Edition Chimaira, Frankfurt am Main, Germany. 408 pp.). There is variation in reports of number of young produced, however, several authors have published a range of 6–20 (Disi et al., *op. cit.*; Sorenson 1988. Bull. Chicago Herpetol. Soc. 23:21–25; Szczerbak 2003. Guide to the Reptiles of the Eastern Palearctic. Krieger Publishing Co., Malabar, Florida. 260 pp.). Bar and Haimovitch (2011. A Field Guide to Reptiles and Amphibians of Israel. Herzilya, Israel. 245 pp.) reported *E. jaculus* parturition occurred in October and November in Israel. In this note I report on a histological examination of *E. jaculus* gonads from Israel in order to ascertain the timing of events of the reproductive cycle.

A sample of 29 *Eryx jaculus* collected in Israel consisting of 7 adult males (mean SVL = 427.1 mm ± 82.7 SD, range = 350–603 mm); 13 adult females (mean SVL = 550.5 mm ± 47.6 SD, range = 493–639 mm); 9 sub-adult females (mean SVL = 436.4 mm ± 35.9 SD, range = 370–473 mm) and deposited in the Natural History Collections of Tel Aviv University (TAUM), Tel Aviv, Israel, was examined. Specimens examined by region were: HaSharon (TAUM 6, 1179, 1675, 2272, 2886, 4069, 8274, 8660, 16761), Jordan Valley (TAUM 4515), Karmel Ridge (TAUM 8), Northern Coastal Plain (TAUM 8661), Northern Negev (TAUM 1414, 1714, 3092, 4532, 9390), Southern Coastal Plain (TAUM 4, 3887, 4573, 4967, 5194, 5937, 16761), Upper Galil (TAUM 14306), Yizreel Valley (TAUM 3, 5, 7, 9). The left testis or ovary was removed, embedded in paraffin and cut into sections of 5 µm. Enlarged ovarian follicles (> 5 mm) were counted. Histology slides were stained with Harris hematoxylin followed by eosin counterstain and were deposited in TAUM.

Three stages were present in the monthly testicular cycle (Table 1): 1) regression, the germinal epithelium in the seminiferous tubules is reduced to a few layers, consisting of spermatogonia and Sertoli cells; 2) recrudescence, there is a proliferation of germ cells for the next period of spermiogenesis. Primary spermatocytes predominate, occasional secondary spermatocytes were noted; 3) spermiogenesis, the lumina of the seminiferous tubules are lined by sperm or metamorphosing spermatids. The period of sperm production occurred in spring-summer (Table 1). This supports the time of mating in the literature for *E. jaculus*: May (Arakelyan et al. 2007. Herpetofauna of Armenia and Nagorno-Karabakh. SSAR, Ithaca, New York. 149 pp.; Valakos et al. 2008. The Amphibians and Reptiles of Greece. Edition Chimaira, Frankfurt am Main, Germany. 463 pp.) or summer (Schleich et al. 1996. Amphibians and Reptiles of North Africa, Biology, Systematics, Field Guide. Koeltz Scientific Publishers, Koenigstein, Germany. 630 pp.). The smallest mature male (spermiogenesis) measured 350 mm SVL (TAUM 2272) and was collected in June.

TABLE 1. Stages in the monthly testicular cycle of 7 adult male *Eryx jaculus* from Israel.

Month	N	Regressed	Recrudescent	Spermiogenesis
February	1	0	1	0
April	1	0	1	0
June	2	0	0	2
July	2	0	0	2
September	1	1	0	0

TABLE 2. Stages in the monthly ovarian cycle of 13 adult female *Eryx jaculus* from Israel. *Follicles were squashed and could not be reliably counted.

Month	N	Quiescent	Enlarged follicles > 5 mm
January	3	2	1
March	2	2	0
May	2	0	2
July	2	2	0
September	1	0	1*
November	1	1	0
December	2	2	0

Two stages were present in the monthly ovarian cycle (Table 2): 1) quiescent, no yolk deposition; 2) enlarged ovarian follicles (> 5 mm). Litters (N = 3) were 6, 9, 10 which to my knowledge, are the first *E. jaculus* litter sizes reported from Israel. The smallest reproductively active female (TAUM 3887) measured 511 mm and was collected in January. One slightly smaller female, SVL = 493 mm (TAUM 1414) was arbitrarily considered to be an adult. Female *E. jaculus* from May and September with enlarged ovarian follicles (Table 2) supports reports in the literature that young are born in summer (Sorenson, *op. cit.;* Lafti 1992. The Snakes of Iran. SSAR, Oxford, Ohio. 159 pp; Stojanov et al. 2011. Die Amphibien und Reptilien Bulgariens, Edition Chimaira, Frankfurt am Main, Germany. 588 pp.; Schleich, *op. cit.*) or autumn (Bar and Haimovitch, *op. cit.*). The presence of four reproductively inactive females of adult size (Table 2), suggests that not every *E. jaculus* female produces young each year. One January female with enlarged follicles (Table 2) suggests it may take as long as six months for an *E. jaculus* female to produce young.

I thank Shai Meiri (TAUM) for permission to examine *E. jaculus*, Erza Maza for facilitating the loan, and the National Collections of Natural History at Tel Aviv University for providing *E. jaculus* for this study.

STEPHEN R. GOLDBERG, Whittier College, Department of Biology, Whittier, California 90608, USA; e-mail: sgoldberg@whittier.edu.

***EUTRACHELOPHIS BASSLERI*. COLORATION AND PHOTOGRAPHS IN LIFE.** *Eutrachelophis basssleri* is a recently described species of a new genus belonging to the family Dipsadidae. Currently, *Eutrachelophis* contains three species—*E. bassleri, E. steinbachi*, and an undescribed species—known from the lowland rainforest in western Amazonia (Myers and McDowell 2014. Bull. Am. Mus. Nat. Hist. 385:1–112). Color in life of *E. bassleri* is only known from field notes (Dixon and Soini 1977. The Reptiles of the Upper Amazon Basin, Iquitos Region, Peru II. Crocodilians, Turtles and Snakes. Milwaukee Public Museum, Wisconsin. 154 pp.) that were used in Myers and McDowell (*op. cit*). Here, we publish the first color photograph of a living specimen, an adult male deposited in the herpetological collection of Centro de Ornitología y Biodiversidad (CORBIDI 09224) from the Chambirillo check point at Cordillera Azul National Park (7.069139°S, 76.015333°W, WGS 84; elev. 1122 m), Picota Province, San Martín Department, Peru, collected on 6 May 2011 by P. J. Venegas.

As can be observed in the photographs (Fig. 1), the specimen has a head that is brown dorsally, rostral scale pale brown, loreal region brown, and labial scales white. A triangular postocular white marking forming a ventrolateral stripe connected with the lateral side of neck collar and nape bearing two conspicuous white ocellar markings. Dorsal surface of neck dark brown, from posterior edge of parietals to a thin incomplete white neck collar; first quarter of the body dark green changing to brown up to the tail; dorsolateral lines of dark spots, conspicuous on first quarter of the body becoming vague and disappearing at the tail; and pale dorsolateral flecks from midbody to the tail. Ventral surfaces white becoming yellow from first third of the body to the tail. Iris dark brown with coppery brown coloration on upper region.

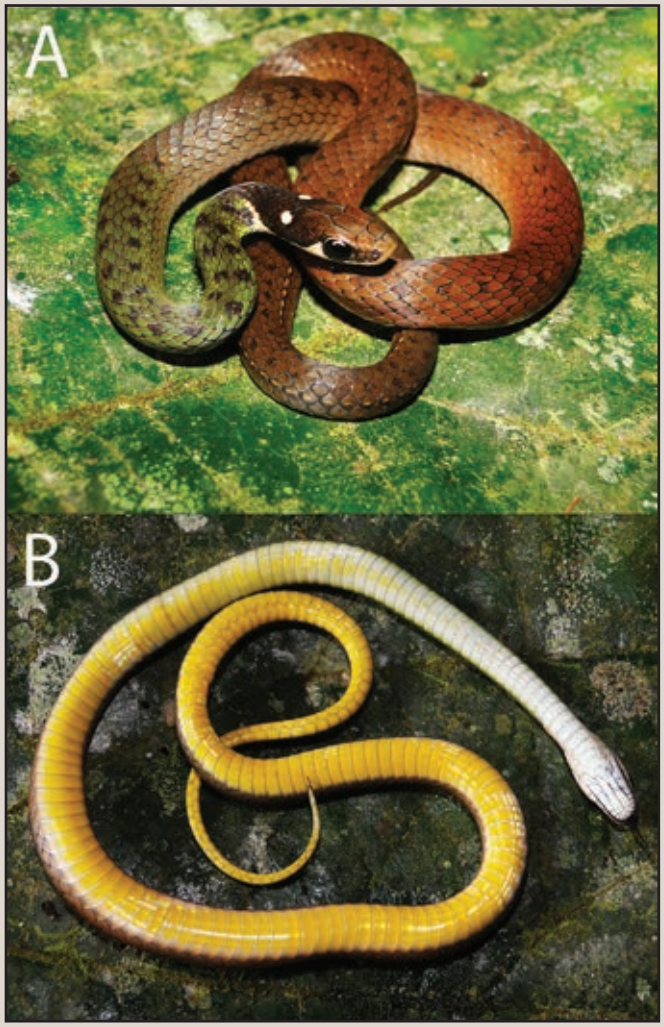

FIG. 1. Dorsolateral and ventral views of *Eutrachelophis bassleri* (CORBIDI 09924), collected at Cordillera Azul National Park, Peru.

This snake was found and photographed thanks to the Servicio Nacional de Áreas Naturales Protegidas por el Estado (SERNANP). We are especially grateful to the rangers P. Saldaña and C. Savedra of SERNANP for their logistic support and company in the field. Fieldwork was supported by a grant from the Mohamed bin Zayed Species Conservation Fund (project number 0925417).

VENEGAS** (e-mail: sancarranca@yahoo.es), División de Herpetología-Centro de Ornitología y Biodiversidad (CORBIDI), Santa Rita No. 105 Of. 202, Urb. Huertos de San Antonio, Surco, Lima, Perú; and Museo de Zoología, Escuela de Ciencias Biológicas, Pontificia Universidad Católica del Ecuador, Avenida 12 de Octubre 1076 y Roca, Apartado 17-01-2184, Quito, Ecuador.

***FARANCIA ABACURA* (Red-bellied Mudsnake). FEEDING BEHAVIOR.** *Farancia abacura* are semi-aquatic colubrid snakes found in the southeastern United States (Ernst and Ernst 2003. Snakes of the United States and Canada. Smithsonian Books, Washington D.C. 668 pp.). Although their diet can consist of frogs and salamanders, *F. abacura* are typically thought to specialize on elongate aquatic salamanders, *Amphiuma* and *Siren* (Guidry 1953. Herpetologica 9:49–56; Gibbons and Semlitsch 1991. Guide to the Reptiles and Amphibians of the Savannah River Site. University of Georgia Press, Athens, Georgia. 131 pp.). Consequently, a feeding event may involve subduing and swallowing prey items that can equal or exceed the snake's body length. Because a prey item equal to the total length of the snake will be approximately 50% longer than the distance from the snake's snout to the end of its stomach (Jackson et al. 2004. Zoology 107:191–200), relatively long prey pose challenges to ingestion and prey storage during digestion. Here we report two observations of feeding behavior that shed light on mechanisms by which *F. abacura* may overcome these challenges.

On the 15 March 2008 at approximately 1330 h, two *F. abacura* were found struggling with an *Amphiuma tridactylum* (Three-toed Amphiuma) at the surface of a large ephemeral pool (ca. 0.5 m deep) at Lake Martin, St. Martin Parish, Louisiana, USA. One snake was biting the amphiuma by the snout while the other snake was biting the tail. While attempting to move the snakes and amphiuma to higher ground for observation, the snake at the tail end of the amphiuma released its hold and escaped. The other snake continued to feed and the event was observed for approximately 2 h in the field before the snake was collected and returned to the lab. The primary mode of prey ingestion appeared to be pterygoid walks with conspicuous lateral movements of the snake's head. Some concertina-like compression and extension of the snake's vertebral column was also observed. When ingestion of the prey item was nearly complete, the Mud Snake regurgitated a significant portion of the meal and immediately began consuming it again. We presume this was to "adjust" the prey, rather than a response to disturbance.

Following the feeding event, the snake (SVL = 675 mm; head width = 14.5 mm) was measured and size of the *A. tridactylum* (total length = 494 mm; diameter = 26.2 mm) was estimated from photographs, yielding an estimated body length ratio of 73% and an ingestion ratio of 180.4% (Greene 1983. Am. Zool. 23:431–441; Jackson et al., *op. cit.*). The following day the snake was x-rayed

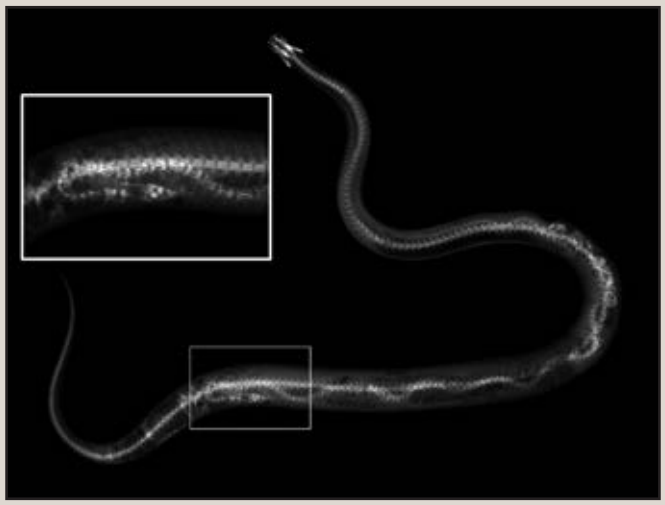

FIG. 1. X-ray of consumed *Amphiuma tridactylum* within the gut of the captured *Farancia abacura*. Note the vertebral waves of the prey item and the hairpin curve near the cervical region.

to examine the orientation of the prey item by Dr. Duane Griggs, DVM, at the Bertrand Drive Animal Hospital in Lafayette, Louisiana. The vertebral column of the amphiuma was compressed into both lateral and horizontal waves with a small hairpin curve in the cervical region (Fig. 1).

On 10 July 2014 at approximately 1000 h, an *F. abacura* (female; SVL = 775 mm; mass = 160.13 g) was captured in a plastic minnow trap set in a floodplain wetland on the U.S. Department of Energy's Savannah River Site, Barnwell Co., South Carolina, USA. At the time of capture, the snake was in the process of swallowing an *Amphiuma means* (Two-toed Amphiuma; SVL = 270 mm; mass = 37.27 g) tail-first. As the *F. abacura* continued swallowing the *A. means* past mid-body, the salamander attempted to bite in defense, but within minutes was completely consumed. Following consumption, the snake was removed from the trap and returned to the laboratory. Approximately 2 h later the snake was processed, which included forcing regurgitation of the prey item. However, regurgitation revealed two surprising results: 1) the *A. means* was still alive, active, and in good body condition; 2) the position of the salamander was now oriented head-first within the snake (i.e., the tail was regurgitated first). Evidently, the position of the *A. means* had completely reversed within the snake's stomach following consumption. It is unclear whether the *A. means* independently changed positions within the snake's stomach or if it was actively manipulated by the *F. abacura* in order to conserve space or facilitate digestion. Nonetheless, folding and compressions of the vertebral column may alleviate some constraints on consuming such long slender prey.

NICHOLAS E. HAERTLE, Department of Biology, University of Louisiana at Lafayette, Lafayette, Louisiana 70503, USA (e-mail: nicholas.haertle@gbcnv.edu); **PAUL M. HAMPTON**, Department of Biology, Colorado Mesa University, Grand Junction, Colorado, USA; **PHILLIP N. VOGRINC** (e-mail: pnvogrin@email.uark.edu), and **JOHN D. WILLSON**, Department of Biological Sciences, University of Arkansas, Fayetteville, Arkansas, USA.

***FARANCIA ABACURA ABACURA* (Red-bellied Mudsnake). REPRODUCTION / COURTSHIP.** Due to the secretive nature of snakes in the genus *Farancia*, reproductive behavior is rarely observed in the wild and courtship behavior has not been reported (Ernst and Ernst 2003. Snakes of the Unites States and Canada. Smithsonian Press, Washington, D.C. 668 pp.). On 15 June 2013, at 1420 h, I discovered a pair of *Farancia a. abacura* ~2 m off of the New Holland Trail at Mattamuskeet National Wildlife Refuge, Hyde Co., North Carolina, USA. The pair was found in a dry section of Bald Cypress forest approximately 80 m from the marsh edge which still contained water. The pair included a large, thick-bodied individual that I assumed to be female and a smaller individual I assumed to be male based on their behavior (Fig. 1A). The male was biting the female mid-body and twisting himself upside down in what appeared to be an attempt to reposition her. He slowly repeated this behavior for ~30 min (with brief pauses and repositioning of himself), biting the posterior portion of the female's body. He used his biting strategy very gently and she made no to attempt to leave the area. They slowly moved around cypress knees and eventually retreated into a pile of leaves and dried Bald Cypress foliage out of sight. Full copulation was not observed; the female did not appear receptive during my observation of the courtship. The male had ~10 small bulging growths on his tail and just anterior to the vent, which could have impeded his ability to copulate (Fig. 1B).

FIG. 1. Courtship of *Farancia abacura* in North Carolina, USA. A) Male biting the female mid-body and twisting to the point that he was upside-down. B) Unidentified bulges that were present on the male, just anterior to the vent.

LANCE PADEN, 8203 Jessup Court, Greensboro, North Carolina 27455, USA; e-mail: lance.paden89@gmail.com.

***HETERODON PLATIRHINOS* (Eastern Hog-nosed Snake). PREDATION.** On 21 September 2014, in Carvers Creek State Park (ca. 1.6 km NE Manchester, Cumberland Co., North Carolina, USA; 35.204170°N, 78.975688°W, WGS84), a partially-eaten juvenile *Heterodon platirhinos* was found pinned on a barbed wire fence, presumably by a Loggerhead Shrike (*Lanius ludovicianus*). The actual predation was not observed, but shrikes are well known for pinning prey in such fashion, and the site was known to be within a shrike's territory; one was observed frequenting the

FIG. 1. Juvenile *Heterodon platirhinos* pinned on barbed wire by Loggerhead Shrike (*Lanius ludovicianus*), Cumberland Co., North Carolina, USA.

FIG. 1. Adult male *Lampropeltis extenuata* from Hernando Co., Florida, exhibiting defensive behavior characterized by a sharply cocked head that is rapidly twitched laterally.

immediate area before and after the snake was found. Loggerhead Shrikes are known to prey on small snakes of several species (Clark 2011. Son. Herpetol. 24:20–22). Previously documented avian predators of *H. platirhinos* include various hawks, owls, and crows (Ernst and Ernst 2003. Snakes of the United States and Canada. Smithsonian Books, Washington, DC. 668 pp.). To our knowledge, this represents the first published report of predation on *H. platirhinos* by a shrike.

***LAMPROPELTIS EXTENUATA* (Short-tailed Kingsnake). DEFENSIVE BEHAVIOR.** *Lampropeltis extenuata* is a state-threatened species endemic to Florida, USA, that inhabits xeric upland habitats from Columbia Co. south to Highlands Co. When first encountered in the wild, a *L. extenuata* will often cock its head sharply upwards with its dark chin facing the observer and then twitch it rapidly from side to side (Fig. 1). Sporadic head twitching can last for several minutes, and it can be elicited again when the snake detects movement by the observer. Woolfenden (1962. Copeia 1962:648–649) mentioned that an excited captive *L. extenuata* would occasionally hold its head vertically and jerk it repeatedly to the side. He speculated that this behavior was related to its fossorial habits, because *L. extenuata* burrows into sand by pressing its nose to the substrate and moving its head up and down. However, burrowing and head-jerking motions differ in their speed and orientation. We believe these rapid lateral head movements mimic those of the *Sistrurus miliarius barbouri* (Dusky Pygmy Rattlesnake), which *L. extenuata* resembles in coloration and pattern, although it is much more slender and has a small head approximately the same diameter as its body. We have frequently observed disturbed *S. miliarius* twitching their upward-angled heads, although we could find no mention of this behavior in the literature. We have also observed this head-twitching defensive behavior in wild-caught *L. calligaster occipitolineata* (South Florida Mole Kingsnakes), another Florida endemic taxon that resembles a robust *L. extenuata.*

In 2013–2014, we found 10 juvenile and adult *L. extenuata* on sand roads during the daytime in April, May, October, November, and December in Hernando (N = 9) and Marion (N = 1) counties. Eight of these snakes remained motionless and exhibited head twitching when approached. An adult male (SVL = 450 mm, total length = 495 mm, 8.2 g) that GC observed being attacked by a *Corvus ossifragus* (Fish Crow) on 30 April 2014 at 0945 h in Hernando Co. (28.6247°N, 82.5060°W; WGS 84) crawled rapidly away after the vehicle flushed the bird. Although this snake did not twitch its head initially, it did so once it stopped fleeing.

Lampropeltis extenuata exhibits other defensive behaviors. The lateral head-twitching behavior is sometimes accompanied by spasmodic tail waggling and curling that resembles the caudal luring performed primarily by juvenile *S. miliarius* (Rabatsky and Waterman 2005. Herpetologica 61:87–91). *Sistrurus miliarius* seldom rattles defensively; its diminutive rattle is relatively ineffective as a warning signal because it is readily shed and produces barely audible rattling sounds when intact (Rowe et al. 2002. *In* Schuett et al. [eds.], Biology of the Pit Vipers, pp. 385–404. Eagle Mountain Publishing, Eagle Mountain, Utah). The defensive tail movements of *L. extenuata* do not resemble the rapid, continuous tail vibrations of many nonvenomous snake species that are thought to deflect attention of a predator away from the more vulnerable head (Greene 1988. *In* Gans and Huey [eds.], Biology of the Reptilia, Vol. 16, Ecology B, pp. 1–151. Alan R. Liss, New York). An excited *L. extenuata* often strikes repeatedly, typically with a closed mouth and a short hiss. These rapid strikes are delivered while the anterior portion of the body is S-shaped, and the posterior portion is partially coiled like a spring or stretched out in a series of tight S-curves. The anterior half of the body often leaves the ground during these lunging strikes. Preparatory to striking, a *L. extenuata* may rapidly bob its head vertically instead of laterally. After a period of time in captivity, these defensive behaviors were seldom observed in *L. extenuata*, except for occasional head twitching when startled or being posed for photographs.

The Florida Fish and Wildlife Conservation Commission granted permission to collect information on wild and captive *L. extenuata.*

KEVIN M. ENGE, Florida Fish and Wildlife Conservation Commission, 1105 SW Williston Road, Gainesville, Florida 32601, USA (e-mail: kevin.enge@myfwc.com); **GARRETT CRAFT**, 15402 Plantation Oaks Drive, Apartment 8, Tampa, Florida 33647, USA; **JORDAN T. SCHMITT,** 5165 S.W. 13th Street, Apartment #331A, Gainesville, Florida 32607, USA; **GLENN L. BARTOLOTTI,** 14001 Middleton Way, Tampa, Florida 33624, USA.

***LAMPROPELTIS POLYZONA* (Milksnake). PREDATION.** It is well known that numerous birds prey on snakes. *Buteo jamaicensis* (Red-tailed Hawks) are known to be generalists, preying on a variety of small and medium mammals, some birds and reptiles; *Accipiter cooperi* (Cooper's Hawks) however, prey primarily on birds; *Buteo plagiatus* (Gray Hawks) prey on lizards, insects and small rodents (Dunn and Alderfer [eds.] 2011. Field Guide to the Birds of North America, 6th ed. National Geographic Society, Washington, DC. 576 pp.). Here, we report an account of predation on *Lampropeltis polyzona* involving these three raptor species in the municipality of Xalisco, Nayarit, Mexico.

On 27 February 2014, a juvenile *L. polyzona* was observed being taken from the ground by an *A. cooperi* in the locality of El Pantanal in the municipality of Xalisco, Nayarit, Mexico (21.417950°N, 104.826449°W, WGS84; elev. 922 m). As the Cooper's Hawk flew with its prey, a *B. plagiatus* knocked the snake back down to the ground. A few seconds later, a *B. jamaicensis* swooped down to the ground, picked up the dead snake, and flew off with the prey. The area surrounding the road was tropical secondary vegetation and sugar cane fields.

JESÚS MAURICIO RODRÍGUEZ-CANSECO (e-mail: jmrc2603@hotmail.com), **KRYSTAL LUCÍA GONZÁLEZ-ESTUPIÑÁN, JOSÉ VILLARREAL-MÉNDEZ, LETICIA ONTIVEROS ESQUEDA,** Centro Universitario de Ciencias Biológicas y Agropecuarias, Universidad de Guadalajara, Zapopan, Jalisco, 45110, México; **ANDREA BOMBELA CRUZ,** Universidad Veracruzana, Xalapa, Veracruz, 91090, México.

***LEPTODEIRA ANNULATA* (Banded Cat-eyed Snake). DIET.** *Leptodeira annulata* is a medium-sized (total length to 600 mm), arboreal, and nocturnal species (Vitt 1996. Herpetol. Nat. Hist. 4:69–76; Ávila and Morais 2007. Herpetol. Rev. 38:278–280), with a wide distribution from Mexico to eastern South America (Duellman 1958. Bull. Am. Mus. Nat. Hist. 5:114–152; Rodrigues 2003. *In* Leal et al. [eds.], Ecologia e Conservacao da Caatinge, pp. 181–236. Ecologia e Conservação da Caatinga, Editora Universitária, Universidade Federal de Pernambuco, Recife, Brazil). The diet is composed mainly of anurans especially those in the families Bufonidae, Hylidae, Leptodactylidae, and Microhylidae (Vitt, *op. cit.*; Cantor and Pizzatto 2008. Herpetol. Rev. 39:462–463). On 29 October 2010, at 2100 h, in Fortuna II farm (9.820056°S, 58.460722°W, WGS 69; elev. 225 m), municipality of Cotriguaçu, state of Mato Grosso, Brazil, we observed an adult *L. annulata* amidst leaf litter ingesting an adult *Leptodactylus mystaceus* (Fig. 1). The frog was caught headfirst, and ingestion took 10 min. Anurans are important prey for a wide variety of vertebrate and invertebrate predators (Toledo et al. 2007. J. Zool. 271:170–177; Oliveira et al. 2013. Herpetol. Notes 6:299–300). Several species of amphibians have been reported as prey of *L. annulata* (Mesquita et al. 2013. Pap. Avul. Zool. 53:99–113; Nascimento et al. 2013. Herpetol. Bras. 2:20–22; Santos-Silva et al. 2014. Herpetol. Notes 7:123–126). Due to their wide distribution and abundance, *Leptodactylus* spp. may represent a significant prey resource for snakes.

FIG. 1. An adult *Leptodeira annulata* preying upon *Leptodactylus mystaceus*, state of Mato Grosso, Brazil.

We are grateful to Conselho Nacional de Desenvolvimento Cientifico e Tecnológico (CNPq)) for providing a fellowship to AFSN, to Fundação Cearense de Apoio to Desenvolvimento Científico e Tecnológico – FUNCAP for are search fellowship to RWA (process BPI-0067-000060100/12) and Coordenação de Aperfeiçoamento de Pessoal de Nível Superior – CAPES for master fellowship to MCS.

***NINIA HUDSONI* (Hudson's Coffee Snake). MAXIMUM SIZE.** *Ninia hudsoni* is a small, leaf litter-inhabiting snake found in the Amazon basin of Ecuador, Peru, and Guyana (Valencia et al. 2009. Herpetozoa 21:190–192). The largest specimen of *N. hudsoni* previously known was 419 mm total length and was collected in Ecuador (Valencia et al., *op. cit.*). On 7 July 2013, I collected a female *N. hudsoni* (Fig. 1) that measured 427 mm total length (SVL = 338 mm; tail length = 89 mm; 21 g). The specimen was found in a pile of wooden boards at approximately 1030 h CST in lower montane secondary forest at Wildsumaco Wildlife Sanctuary in eastern Napo Province, Ecuador (0.68745°S, 77.60076°W, WGS84; elev. 1427 m). The specimen (QCAZ 11991) was deposited in the Museo de Zoologia of the Pontificia Universidad Catolica del Ecuador in Quito.

I am especially grateful to my Ecuadorian collaborators Santiago Ron and Omar Torres for aid during all aspects of the work. James Olson, Bonnie Olson, and Jonas Nilsson generously allowed access to the Wildsumaco property.

FIG. 1. Dorsal view of an extremely large *Ninia hudsoni* (QCAZ 11991) from Napo Province, Ecuador.

JEFFREY D. CAMPER, Department of Biology, Francis Marion University, Florence, South Carolina 29506, USA; e-mail: jcamper@fmarion.edu.

***OPHEODRYS VERNALIS* (Smooth Greensnake). NEST SITE SELECTION.** *Opheodrys vernalis* is a poorly known colubrid with a patchy, largely boreal distribution in the United States (Ernst and Ernst 2003. Snakes of the United States and Canada. Smithsonian Press, Washington, D.C. 668 pp.). This snake is considered primarily terrestrial, showing little inclination to climb (Conant and Collins 1998. A Field Guide to Reptiles and Amphibians of Eastern and Central North America. 3rd ed., expanded. Houghton Mifflin Co., Boston, Massachusetts. 616 pp.). Reported nest sites have been limited to terrestrial habitats, such as rotting logs (Cook 1964. Herpetologica 20:206), sandy soils (Fowler 1966. Herpetologica 22:231), grassy fields (Sexton and Claypool 1978. J. Nat. Hist. 12:365–370), and garbage bags (Lawson 1983. Herpetol. Rev. 14:20). Here we report an arboreal oviposition site for *O. vernalis*.

At 920 h on 27 May 2013, in the northwestern part of the Powdermill Nature Reserve, Westmoreland Co., Rector, Pennsylvania, USA (40.163707°N, 79.267080°W, WGS84; elev. 460 m), we captured a gravid female *O. vernalis* (SVL = 35 cm; tail length = 14.5 cm; 6 oviductal eggs) on a tree, emerging from a crevice of decaying bark, 1.5 m above the ground (Fig. 1). At 1020 h on 4 June 2013 the female was recaptured at the same location. Upon recapture, the female was no longer gravid and a clutch of eggs was observed inside the opening in the tree. During release of this individual, a second gravid female *O. vernalis* (SVL = 35.5 cm; tail length = 14 cm; 8 oviductal eggs) was detected in the same crevice of the tree. Neither female was recaptured during subsequent surveys at the site. Yet, a larger assemblage of eggs (> 6) was observed in the tree crevice after the second female was released, likely indicating communal nesting. To avoid disruption of natural embryonic development, the eggs in the tree were not counted or moved.

Communal nesting is common in *Opheodrys* spp. (Graves and Duvall 1995. Herpetol. Monogr. 9:102–119). However, oviposition sites differ between species and likely reflect the arboreal or terrestrial lifestyles of *O. aestivus* (Rough Green Snake) and *O. vernalis*, respectively. Nest sites of *O. aestivus* have been characterized as narrow vertical slits in tree interiors as a result of rotting (Plummer 1990. Herpetologica 46:190–195). The arboreal nesting behavior and nest sites of *O. aestivus* described by Plummer (*op. cit.*) are analogous to our observations of *O. vernalis*. To the best of our knowledge this report represents the first record of an arboreal nest site for *O. vernalis*.

FIG. 1. Gravid female *Opheodrys vernalis*, exhibiting arboreal behavior leading to a previously undocumented nest site for the species, Westmoreland Co., Rector, Pennsylvania, USA.

We thank the staff of the Powdermill Nature Reserve (PNR) and the Carnegie Museum of Natural History, especially the Director of PNR, John W. Wenzel.

***PTYAS NIGROMARGINATA* (Green Ratsnake). DIET.** Despite the wide geographic range of *Ptyas nigromarginata* and its attention in systematics research (Vogel and Hauser 2013. Asian Herpetol. Res. 4:166–181), very little was known about its natural history. The known diet of *P. nigromarginata* includes only rodents and anurans (Zhao et al. 1998. Fauna Sinica Reptilia Squamata Serpentes. Science Press, Beijing. 522 pp.).

At 1339 h on 3 July 2013, an adult *P. nigromarginata* was observed and photographed swallowing an adult female *Japalura yunnanensis* (Yunnan Mountain Lizard) along a country road near Zhiziluo Village of Fugong County, Nujiang Lisu Autonomous Prefecture, western Yunnan Province, PR China (Fig. 1). The snake fled with the prey in its mouth shortly after the image was taken. This record adds lizards to the natural diet of *P. nigromarginata*.

FIG 1. Adult *Ptyas nigromarginata* swallowing an adult female *Japalura yunnanensis* in Fugong County, western Yunnan, PR China.

***SISTRURUS CATENATUS* (Massasauga). DIET.** On 20 June 2014 we found a road-killed sub-adult (mass = 22.7 g) female *Sistrurus catenatus* on a sandy access road in Kalkaska Co, Grayling, Michigan, USA. During necropsy, a damselfly (suborder Zygoptera) nymph was discovered in the snake's stomach (T. Cooley, pers. comm.). Given the range of taxa reported as *S. catenatus* prey items, it is apparent that this species is a fairly indiscriminate predator (Ernst and Ernst 2003. Snakes of the United States and Canada. Smithsonian Books, Washington, DC. 668 pp.). To our knowledge, this is the first instance any damselfly species has been recorded as part of the diet for *S. catenatus*. The damselfly was the only item in the snake's gut, so it is not likely the result of secondary ingestion. As damselfly nymphs are fully aquatic,

it is especially interesting that a *S. catenatus*, a terrestrial snake, consumed one. However, this species is known to swim and consume other aquatic prey (Ernst and Ernst, *op. cit.*).

We thank the Michigan Department of Military and Veterans Affairs, the Michigan Society of Herpetologists, and the Fort Wayne Children's Zoo for project funding, and Thomas Cooley and collaborators at the Michigan DNR Wildlife Disease Laboratory for necropsy assistance. All research was conducted under a Scientific Collector's permit from the Michigan Department of Natural Resources and an approved Purdue Animal Care and Use Committee protocol.

KINGSBURY**, Department of Biology, Indiana University-Purdue University Fort Wayne, 2101 East Coliseum Boulevard, Fort Wayne, Indiana 46805, USA; **JENNA M. PARKER,** Department of Fish, Wildlife, and Conservation Biology, Colorado State University, 1474 Campus Delivery, Fort Collins, Colorado 80523, USA.

***SISTRURUS CATENATUS* (Massasauga). OVERWINTERING SITE.** On 12 April 2014 in Kalkaska Co., Grayling, Michigan, USA, we observed an adult *Sistrurus catenatus* overwintering inside a PVC pipe (pipe length = 152.0 cm, diameter = 5.0 cm). The pipe extended vertically over a meter into the ground, was open on top and the lip protruded 3.0 cm from the ground surface. It had been placed near a known hibernaculum several years ago to allow monitoring of water table depth (Smith 2009. MS Thesis, Purdue Univ., Fort Wayne. 61 pp.). The *S. catenatus* was mostly submerged in groundwater, which was 19.0 cm below the opening of the pipe (Fig. 1). When approached, the snake retreated under the water. While this individual appeared to be alone, it was ca. 3 m from a natural burrow where we observed at least three *S. catenatus* and two *Thamnophis sirtalis sirtalis* (Eastern Gartersnakes) communally overwintering. No telemetered *S. catenatus* had yet emerged from overwintering, and thus it was unlikely that the snake in the tube had moved there recently. When we returned to the location on 26 April 2014, the *S. catenatus* was no longer in the pipe, suggesting it had successfully emerged.

Although several snake species have been previously recorded overwintering in anthropogenic structures (Shoemaker et al. 2009. *In* Mullin and Seigel [eds.], Snakes: Ecology and Conservation, pp. 221–243. Cornell University Press, New York), this is the first time a *S. catenatus* has been recorded overwintering in a PVC pipe. Considering that artificial overwintering site construction may have utility as a conservation strategy, further research employing PVC pipes in a more systematic manner is warranted.

FIG. 1. A *Sistrurus catenatus* overwintering inside a PVC pipe in Kalkaska Co., Michigan, USA.

We thank Kristin Tetzlaff for field assistance and photographs. Funding was provided by the Michigan Department of Military and Veterans Affairs, the Michigan Society of Herpetologists, and the Fort Wayne Children's Zoo. All research was conducted under a Scientific Collector's permit from the Michigan Department of Natural Resources and an approved Purdue Animal Care and Use Committee protocol.

MICHAEL J. RAVESI (e-mail: ravemj01@ipfw.edu), **SASHA J. TETZLAFF,** and **BRUCE A. KINGSBURY**, Department of Biology, Indiana University-Purdue University Fort Wayne, 2101 E. Coliseum Boulevard, Fort Wayne, Indiana 46805, USA.

***SISTRURUS MILIARIUS BARBOURI* (Dusky Pygmy Rattlesnake). ALBINISM.** On 30 June 2014, two amelanistic and three normal phenotype *Sistrurus miliarius barbouri* neonates were observed in a screened-in enclosure behind a building in Lee Co., Florida, USA (Fig. 1). The mother had been observed in the area for a couple of months and was present with her offspring, which had apparently already undergone postnatal ecdysis. On 1 July, a third amelanistic neonate was observed (Fig. 1). The background color of the amelanistic neonates was pale pink, and the dorsal blotches were a pale yellowish orange separated by reddish orange pigment. The snakes were photographed in situ and not disturbed. The equal sex ratio of amelanistic and normal-colored neonates in the litter suggests that the father was amelanistic. Albinism has not been reported in *Sistrurus*, but an amelanistic adult was captured south of Tampa, Pinellas Co., Florida, in 2013 and died in captivity (Paul Moody, pers. comm.).

FIG. 1. Three amelanistic *Sistrurus miliarius barbouri* neonates observed in Lee Co., Florida, USA.

KEVIN M. ENGE, Florida Fish and Wildlife Conservation Commission, 1105 SW Williston Road, Gainesville, Florida 32601, USA (e-mail: kevin.enge@myfwc.com); **KATHLEEN SMITH**, Florida Fish and Wildlife Conservation Commission, 23998 Corkscrew Road, Estero, Florida 33928, USA (e-mail: kathleen.smith@myfwc.com).

***TANTILLA SUPRACINCTA* (Banded Centipede Snake). REPRODUCTION.** *Tantilla supracincta* is known from Nicaragua to central Panama, south to western Ecuador (Savage 2002. The Amphibians and Reptiles of Costa Rica, a Herpetofauna Between Two Continents, Between Two Seas. University of Chicago Press, Chicago, Illinois. 934 pp.). Other than being oviparous, the reproductive cycle of *T. supracincta* is unknown (Solórzano 2004. Snakes of Costa Rica, Distribution, Taxonomy and Natural History. Instituto Nacional de Biodiversidad, Santo Domingo de Heredia, Costa Rica. 791 pp.). The purpose of this note is to present the first reproductive data for *T. supracincta*.

Two female *T. supracincta* from Costa Rica were examined from the herpetology collection of the Natural History Museum of Los Angeles County (LACM), Los Angeles, California, USA. One oviductal egg was found in LACM 154396 (SVL = 282 mm) collected November 1974 at the vicinity of Palmar Norte (8.96666°N, 83.46666° W, WGS 84), Puntarenas Province. The right ovary of LACM 154398 (SVL = 252 mm) collected June 1964 at Silencio (10.16500°N, 84.47194°W, WGS 84), Guanacaste Province was removed for histological examination. Histological sections were cut at 5 µm and stained with hematoxylin followed by eosin counterstain. Microscopic examination revealed it had commenced yolk deposition as evidenced by basophilic granules in the ooplasm. The histology slide was deposited in LACM. One is the first reported clutch size for *T. supracincta*.

I thank G. Pauly (LACM) for permission to examine *T. supracincta*.

STEPHEN R. GOLDBERG, Whittier College, Department of Biology, Whittier, California 90608, USA; e-mail: sgoldberg@whittier.edu.

***THAMNOPHIS PROXIMUS* (Western Ribbonsnake). REPRODUCTION.** *Thamnophis proximus* ranges from Wisconsin, Indiana, and the Mississippi Valley to Colorado and New Mexico, southward through eastern Mexico to central Costa Rica (Rossman 1970. Cat. Amer. Amphib. Rept. 98.1–98.3). The reproduction of *T. proximus* has been well-studied in North America (Tinkle 1957. Ecology 38:69–77; Clark 1974. Herpetologica 30:372–379) however information on reproduction of this species in Central America is limited. Neill 1962. (Quart. J. Florida Acad. Sci. 25:234–253) reported a litter of six for *T. proximus* (as *T. sauritis rutiloris*) born in July in Belize. In this note I report two litter sizes for *T. proximus* from Nicaragua.

Five female *T. proximus* from Nicaragua were examined from the herpetology collection of the Natural History Museum of Los Angeles County, Los Angeles, California, USA: LACM 21036 (Región Autónoma del Atlántico Norte); 38082 (Managua Department); 38084, 38085 (Jinotega Department); 38089 (Rivas Department). Two females were reproductively active: LACM 21036, collected February 1962 (SVL = 382 mm) contained six enlarging follicles (> 7 mm); LACM 38089, collected November 1966 (SVL = 407 mm) contained eight developing embryos. Ernst and Ernst (2003. Snakes of the United States and Canada. Smithsonian Books, Washington, D.C. 668 pp.) reported parturition in *T. proximus* occurred from late June to early October, with most neonates born from July to early September. The presence of *T. proximus* female reproductive activity in February and November suggests an extended reproductive cycle in Nicaragua in comparison to North America (Tinkle, *op. cit.*; Clark, *op. cit.*).

I thank G. Pauly (LACM) for permission to examine *T. proximus*.

STEPHEN R. GOLDBERG, Whittier College, Department of Biology, Whittier, California 90608, USA; e-mail: sgoldberg@whittier.edu.

***THAMNOPHIS SAURITUS SACKENII* (Peninsula Ribbonsnake). DEFENSIVE BEHAVIOR / DEATH FEIGNING.** Death-feigning behavior (thanatosis) is best known in Hog-nosed Snakes (*Heterodon* spp.) but has been reported in other snake genera (Gehlbach 1970. Herpetologica 26:24–34). On 3 February 2015, an adult female *Thamnophis sauritus sackenii* (SVL = 438 mm) was found on a sidewalk in Gainesville, Alachua Co., Florida, USA. When picked up, the snake thrashed vigorously with its mouth open. Approximately 30 sec after being restrained, the snake ceased moving, becoming stiff and unresponsive in a contorted position (Fig. 1). Snakes feigning death typically gape and may extrude their tongues; their limp bodies may be partially or totally supine (inverted) (Gehlbach, *op. cit.*). Death feigning by the *T. sauritus* was unusual in that its mouth remained closed and its body exhibited total rigor when experimentally placed in various positions for ca. 5 min before being placed in a cloth bag. The *T. sauritus* behaved normally when examined 1 h later. During two weeks in captivity, it would thrash with its mouth open when grasped firmly but failed to feign death when I tried replicating the initial capture events. I could find only one report of tonic immobility in *Thamnophis*. When released after handling, some *T. elegans* (Terrestrial Gartersnakes), particularly gravid females, remained immobile, sometimes on their backs, for up to 10 min (Gregory and Gregory 2006. J. Comp. Psychol. 120:262–268). *Natrix natrix* (Grass Snake) is also in the subfamily Natricinae, and 66% of wild-caught specimens feigned death, with the most dramatic cases involving voluntary supination and/or lack of muscle tone (Gregory et al. 2007. J. Comp. Psychol. 121:123–129).

FIG. 1. Death feigning by an adult female *Thamnophis sauritus sackenii* that kept its mouth closed and its body rigid for at least 5 min.

KEVIN M. ENGE, Florida Fish and Wildlife Conservation Commission, 1105 SW Williston Road, Gainesville, Florida 32601, USA; e-mail: kevin.enge@myfwc.com.

ADDENDUM—In a recent natural history note concerning the interaction of *Hydrophis platura* (Yellow-bellied Seasnake) with Bottlenose Dolphins (Durso et al. 2015. Herpetol. Rev. 46:104), we overlooked an earlier report of similar behavior involving the same two species (Ineich and Loyer 1998. Bulletin de la Société des Études Océaniennes 276:86). We thank Ivan Ineich for bringing this earlier publication to our attention.

e-mail: lgrismer@lasierra.edu

During the last two decades the known Thai herpetofauna has much increased due to new species descriptions and to additions of species recorded from neighboring countries, and species are still regularly added today (Kunya et al. 2015; Pauwels et al. 2015; Sumontha et al. 2015). The Thai reptile list is also still going through important taxonomic changes (see the most recent change by David et al. 2015). Under these circumstances, one might wonder if this was the best time to produce a field guide. On the other hand, existing guides on the Thai herpetofauna are really outdated or incomplete (David et al. 2004; Pauwels and David 2005, 2011), and an easily accessible update on the current status of knowledge on the reptiles of Thailand would certainly be good support for further research and conservation management.

This courageous task of compilation has been jointly attempted by three authors. Tanya Chan-ard has dedicated his whole career to the study of the reptiles and amphibians of Thailand, and his field knowledge on these faunas is unrivalled. John Parr is a conservationist with experience in Southeast Asia but is not a herpetologist, hence his participation in such a challenging enterprise is a surprise. Jarujin Nabhitabhata was one of the leaders in herpetological research in Thailand, but he tragically died during minor surgery in 2008 (Chan-ard et al. 2009), i.e., seven years before the guide under discussion here was published.

The guide's size makes it easy to bring in the field, with good quality binding and paper. It is divided into six main parts: an unnamed section (pp. i–xxix) including a glossary and a key to the major groups of Thai reptiles; an introduction (pp. 1–17) containing a history of herpetology in Thailand; a half-page section on physiography; very general sections on habitats (without figures), zoogeography, and conservation; species accounts (pp. 18–298); a selected bibliography (pp. 299–306); an index of scientific names and an index of common names. The authors included keys to genera for most families, and keys to species within each multiple-species genus.

The glossary does not include a number of terms that are used in the identification keys (alveolar rim, amphicoelian, cornified, entoplastron, pentadactyl, pores, precentral scute, pterygoideum, etc.). Some of the glossary's definitions are erroneous or misleading (for example "anal plate" is defined as the "terminal ventral scale or scute" while the drawing on page xxix mentions that the last ventral precedes the anal; "scansorial" is defined as "both arboreal and terrestrial;" "superciliary" is defined as "small scale bordering orbit"). No methodology is provided to explain how to count supralabials, infralabials, lizard midbody scales, etc. There is no distinction made between snake preventrals and ventrals (see drawing p. xxviii). The way shown to measure the plastron length (p. xxv) is erroneous.

The section on the history of herpetology in Thailand is a major disappointment. The guide being co-authored by two Thai herpetologists, one would have hoped to find much information on the contributions by their compatriots. However, after long paragraphs dedicated to the biography of foreign herpetologists, including only information already available in the literature, the single thing said about Thai herpetologists is "currently, there are about 20 Thai nationals with a keen interest in herpetology supported by a network of more than 100 experts in particular field of hepetological [sic] taxonomy"! Not a single word about pioneers such as the late Wirot Nutphand who wrote the first Thai reptile guides and described several taxa including the iconic *Chitra chitra*, Kumthorn Thirakhupt who trained a large part of the current generation of Thai herpetologists, Lawan Chanhome who made significant progress in the study of Thai snake venoms and husbandry, Piboon Jintakune who initiated an important snake reference collection at the Thai Red Cross, Yodchaiy Chuaynkern or Montri Sumontha, to mention a few. There is not even a mention of the fact that Jarujin died in 2008!

The habitats and zoogeography sections of the introduction are very general and make a single reference to reptiles ("turtle") but refer five times to mammals; its seems like these sections have been just copied and pasted from a general guide on Thai mammals. The map showing the Thai provinces is outdated, and Bueng Kan Province, cited in the guide, won't be found on the map.

Within the families, the order of genera seems more or less random, as does the order of species within genera, making it very impractical to find a given taxon. The text for the family Typhlopidae has been placed by mistake in the Sauria section. The introduction to Agamidae tells us that this family includes the genus *Takydromus*!

The key to the major groups of Thai reptiles states that in lizards "the tail is equal to or longer than snout-vent length (unless regenerated);" this obviously does not always apply, for example, to *Dibamus* and some *Isopachys*. The keys to trionychid and skink genera are largely based on osteological characters, inappropriate for a field guide. The key to genera of the Geoemydidae lacks an entry to couplet 4, and the key is partly based on osteological characters. The key to the genus *Malayemys* erroneously states that the front of the upper jaw of *M. subtrijuga* has three vertical lines, while it actually has three pairs of vertical lines. The key to the lizard families erroneously states that all legless skinks have an ear-opening and implies that Anguidae do not. The keys to trionychid genera, agamid genera (*Acanthosaura*, *Calotes*, *Draco*, *Pseudocalotes*), gekkonid genera (*Cnemaspis*, *Cyrtodactylus*, *Dixonius*, *Ptychozoon*), skink genera (*Eutropis*, *Isopachys*, *Scincella*, *Sphenomorphus*), *Dibamus*, *Boiga*, *Oligodon*, Crotalidae, *Disteira*, homalopsid genera, *Asthenodipsas*, etc., contain numerous mistakes regarding character variation, with considerable discrepancies between variation given in the species accounts, variation given in the keys, and characters visible on the drawings. One of many examples is that the character "no gular fold or pouch" leads to *Aphaniotis* in the key to agamid genera, but the species account for *A. fuscus* mentions "the gular pouch is black." The first choice in the agamid genera key is between "body depressed" and "body compressed"—the first leads, after some additional steps, to *Leiolepis*, while the account for that genus states "members of this genus have a compressed body," in complete contradiction with the key. The last point of the key for *Bronchocela* leads to *B. cristellata*, the last point of the key to *Xenochrophis* leads to *X. flavolineatus*, while these two species don't exist. There is no key to snake families nor to colubrid genera. There is no drawing nor definition to explain the peculiar head scales of the scolecophidians, rendering the use of their key very difficult. The key to Hydrophiidae lacks an entry to couplet 11, and does not include the genus *Praescutata*, which is, however, recognized by the authors. The key to *Dendrelaphis* does not include *D. subocularis*, which is, however, included in the guide. These very numerous mistakes and missing keys will make the identification of sea turtles, terrapins, softshell turtles, skinks, and of all snakes particularly challenging. It should be noted that the body lengths of *Laticauda colubrina* and *Trimeresurus sumatranus* are erroneously indicated at 360 cm and 256 cm, respectively.

Relative species' sizes within genera are often inconsistent. For example *Lycodon fasciatus* is said to have a body length of 89.5 cm and be a medium-sized snake, while *L. cardamomensis* is said to have a body length of 89.6 cm and be a small snake. *Oligodon catenatus* is said to have a body length of up to 60.7 cm and to be "one of the larger Kukri snakes," while *O. fasciolatus* is said to have a body length of up to 80.7 cm and to be a "small Kukri snake."

A number of important references cited in the text are not included in the literature section. The literature section includes 156 references (one is listed twice), i.e., only a small part of the existing literature on Thai reptiles. The arrangement of references is not consistent: it is sometimes purely by alphabetical order, sometimes by chronological order within a series of references with the same first author, thus not following strict alphabetical order. The selection of references is mysterious, as many major revisions and herpetofaunal inventories are missing, while many obsolete and insignificant contributions were included, even several publications that deal exclusively with Thai amphibians. The introduction of the guide explains that it "includes species accounts for all of the 352 reptile species currently with confirmed records in Thailand as of December 31, 2010." However, there is only one reference for 2010—the revision of the Thai *Cnemaspis* by Grismer et al., in which seven new species were described, of which only one, *C. narathiwatensis*, was included in the guide! For 2009 there is also only a single reference listed, the description by Bauer et al. of *Cyrtodactylus erythrops*, a species that was, however, not included in the guide! For 2008, the authors listed only five references (not repeated in the literature cited below), including Bauer et al. (2008) who described *Gekko nutaphandi* from Kanchanaburi Province, David et al. (2008) who described *Oligodon pseudotaeniatus* from central Thailand, and Grismer et al. (2008) who described *Cnemaspis biocellata*—but none of these species was included in the guide! The authors also listed Murphy et al. (2008) who rediscovered and redescribed *Parataphinophis praemaxillaris* giving a maximal known snout–vent length of 770 mm, while in the guide it is stated "a very small snake …body length: up to 22.7 cm"! With only two references for 2009 and 2010 combined, and five references for 2008 that have not been integrated in the text, it would thus have been more honest to write that the literature was included until the end of 2007, even if many important references are also missing for that year. The authors gave the number of Thai protected areas "as of December 2008." Thus, there is a gap of about seven years between the finalization of the guide contents and its publication.

The guide is totally outdated regarding snake and lizard classification, having not benefitted from the numerous phylogenies and revisions published in the 2010s. For example, snake genera like *Aplopeltura*, *Pseudoxenodon*, *Sinonatrix* and even *Xenodermus* are still included in the Colubridae in the guide and the anguid *Dopasia gracilis* is still under *Ophisaurus*. The classification used in the guide thus gives an outdated picture of the currently recognized taxonomic diversity of Thai reptiles.

Among the 352 species presented, 22 (ca. 6%) were not illustrated (*Draco haematopogon*, *Sphenomorphus grandisonae*, *S. helenae*, *S. lineopunctulatus* and *S. mimicus*, *Argyrophis roxaneae*, *Indotyphlops ozakiae*, *Lycodon butleri*, *Oligodon jintakunei*, *Acalyptophis peronii*, *Chitulia bituberculata*, *C. inornata* and *C. lamberti*, *Disteira nigrocincta*, *Hydrophis obscurus*, *Microcephalophis cantoris*, *Polyodontognathus caerulescens*, *Thalassophis anomalus*, *Enhydris chanardi*, *Opisthotropis spenceri*, *Xenochrophis punctulatus,* and *Plagiopholis blakewayi*). Drawings vary greatly in quality from one species to another, probably because they were executed by three different artists (there is no indication as to which artist made what drawings). Sometimes several specimens are illustrated for a single species, differing from each other, but as there are no figure captions, one does not know if the differences correspond to age, sexual dimorphism, breeding condition, subspecific or individual variation. The drawings of pitvipers, *Boiga* spp. and cobras are superb and deserve special mention. The drawing for *Cyrtodactylus sumonthai* definitely does not illustrate that species. *Gonyosoma floweri*, a brown morph of *G. oxycephalum* (David et al. 2004), is however recognized as a distinct species in the guide, but illustrated with a drawing of *Orthriophis taeniurus ridleyi*. The drawings of *Gongylosoma longicauda* and *Liopeltis tricolor* have been mixed up, as well as the drawings of *Oligodon joynsoni* and *O. taeniatus*. These are obvious, but there may be others, as there are very numerous discrepancies between the color descriptions in the species accounts and the drawings. In the era of digital photography, drawings should be used only if they offer something more than

photographs, such as accurate scalation outlines or color variations that are not available on photographs.

Species missing in the guide include at least the agamids *Acanthosaura cardamomensis*, *Pseudocalotes kakhienensis,* and *P. khaonanensis*, the gekkonids *Cnemaspis biocellata*, *C. chanardi*, *C. huaseesom*, *C. kamolnorranathi*, *C. niyomwanae*, *C. omari*, *C. punctatonuchalis,* and *C. vandeventeri*, *Cyrtodactylus astrum*, *C. auribalteatus*, *C. doisuthep*, *C. dumnuii*, *C. erythrops*, *C. inthanon*, *C. khelangensis*, *C. kunyai*, *C. lekaguli*, *C. macrotuberculatus*, *C. phuketensis*, *C. ranongensis*, *C. saiyok*, *C. samroiyot*, *C. sanook*, *C. surin,* and *C. wangkulangkulae*, *Gekko lauhachindai* and *G. nutaphandi*, *Hemiphyllodactylus chiangmaiensis,* and *Ptychozoon kaengkrachanense* (see, for example, Grismer et al. 2010, 2012, 2014), the skinks *Jarujinia bipedalis*, *Larutia nubisilvicola*, *Lygosoma angeli,* and *L. frontoparietale* (this last species is in the identification key for the genus, but its species account has been omitted), the colubrids *Dendrelaphis nigroserratus*, *Lycodon ophiophagus*, *Oligodon pseudotaeniatus,* and *Ptyas nigromarginata,* the homalopsids *Cerberus schneiderii* and *Homalopsis mereljcoxi*, the natricids *Amphiesma boulengeri*, *A. leucomystax,* and *Sinonatrix yunnanensis,* and the viperids *Trimeresurus cardamomensis* and *T. phuketensis*. There is no mention of the emydid *Trachemys scripta elegans* and the trionychid *Pelodiscus sinensis*, although both have been abundantly released in the wild in Thailand, and are possibly locally reproducing (Vidthayanon 2005).

Leiolepis ocellata, regarded as a subspecies of *L. belliana* in the guide, was raised to species level by Pauwels and Chimsunchart (2007). Without any justification, a number of subspecies are not recognized in the guide, such as those of *Oreocryptophis porphyraceus*. *Dryocalamus davisonii tungsongensis* is recognized in the guide as a subspecies of *D. subannulatus*, while these taxa had been synonymized in a work coauthored by Tanya Chan-ard (Pauwels et al. 2006). There are many more taxonomic comments that could be made, but this would go far beyond the scope and the space allowed for a book review.

The section "Identification of Reptiles" states that the "international conservation status is provided at the end of each species account," while this section appears in only 44 (12.5%) of the species accounts. For these species this section only mentions the IUCN and/or the CITES category, without any comment, thus not explaining what threats the species face. In some cases the IUCN conservation status attributed has been made up ("Insufficiently Known" p. 23 [presumably "Data Defficient"]). The guide, thus, does not provide any new information on the conservation status of Thai reptiles and does not even present the data already available on the subject, with the exception of the CITES and IUCN listings as they were in 2007.

Based on the available published literature, it is obvious from the first look that more than a fourth of the maps presented in the guide are grossly incomplete or erroneous. There are numerous contradictions between the text and the maps; one among many examples is found in *Batagur borneoensis*, where the text says it inhabits in Peninsular Thailand as far north as Bangkok while the map shows a distribution in Thailand limited to Yala Province.

There are serious mistakes in the behavior and habitat sections within some species accounts. For example *Cyrtodactylus tigroides* is indicated as a cave-dweller (this mistake is also in the identification key for the genus); its common name is even given as "Tiger Cave Gecko." Regarding *Draco blanfordii*, the authors stated "prefers hilly habitats, although young are found at lower elevations." *Leiolepis* are presented as insect-eaters, there is no mention of the fact that their diet also includes plants.

The index to common names is extremely impractical. For example, the Selangor Striped Skink can be found only under "Skink, Striped, Selangor"; there is no entry under Striped or Selangor. In the conservation section of the introduction, the common names for seven species differ from the ones used in their respective species accounts; only the latter names are in the index. In the index to common names, a number of common names differ from the names appearing in the species account, among others the Slender Blind Snake name found in the species account is replaced by the Doi Pui Blind Snake in the index. The common name Malayan Snail-eating Turtle is applied to *Malayemys subtrijuga* in the introduction, and to *M. macrocephala* in its species account; in the latter case it is definitely an inappropriate common name given the species' distribution. Other inappropriate common names include "Tailed Skinks" for *Plestiodon*, "Western Legless Skink" for *Isopachys borealis*, or "Clouded Pit Viper" for *Trimeresurus nebularis*, the two latter being based on misunderstandings of the species' scientific epithets. The common name "Common Softshell Turtle" is given for the genus *Amyda* which contains a single species, but that species receives the name "Asiatic Softshell Turtle," none of these names appear in the index. Throughout the guide there is a disturbing lack of consistency regarding the common names when they are used without the corresponding scientific name, making it often impossible to deduce what species the authors were writing about. The index to scientific names is badly designed, with entries to genera then species within genera, not entries to species, which makes it more difficult for readers who do not know to which genus a species they are looking for currently belongs.

Oxford University Press is to be held responsible as much as the authors for the numerous shortcomings of the guide. Even a very superficial review of the manuscript by a non-specialist would have revealed that the data are seven years old and thus mostly outdated, that mistypings, not limited to scientific names, are numerous (more than 280), that all figure captions are missing, that many of the references cited in the text are not in the bibliography, that 79% of the references in the bibliography are not mentioned in the main text, that some numberings within identification keys are wrong, etc. A slightly more careful review would have shown that even the 2008 status of knowledge on Thai reptiles is not properly reflected in the guide. Because about 50 species from at least seven families are missing, many identification keys are erroneous or obsolete, the taxonomy and the conservation data are outdated and many maps are incomplete or erroneous, and in spite of the obvious efforts the authors have put into the making of this good-looking book, we definitely cannot recommend the use of this guide. We hope that a new, completely revised version will soon be produced.

Acknowledgments.—We thank Tanya Chan-ard, Michael Cota, M. Jack Cox, Patrick David, and Mike Dloogatch for useful discussions.

e-mail: richard.wassersug@ubc.ca

One can't help but marvel at a scholar who can stick with a challenging project for close to half a century. In 1970, Ronald Altig published "A key to the tadpoles of the continental United States and Canada" in the journal *Herpetologica*. The key was neither perfect nor complete. Altig was determined to make it better. Now, after 45 years of commitment, his original 27-page paper has expanded into a 368-page book. This volume culminates a productive career and is a profoundly comprehensive work.

Altig's co-author on the book, Roy McDiarmid, has not spent his career so singly focused on amphibian larvae, but has spent much of the last 20 years studying tadpoles. The collective devotion of Altig and McDiarmid was first demonstrated by their important reference book, *Tadpoles: The Biology of Anuran Larvae*, published 16 years ago (McDiarmid and Altig 1999).

Many more species are included in this new book than in Altig's 1970 key. Most of those result from legitimate revisions or discovery of cryptic species. Other species are exotics that now make their home not only in the continental United States, but also in Hawaii.

The title of this book does not do justice to its depth and breadth. For example, it doesn't mention the 40 pages dedicated to a key to the eggs and embryos of amphibians. The book also includes a detailed glossary and a huge literature cited section. Species accounts for all amphibian taxa currently recognized in North America are included, organized by family. Each species account includes information under the headings: Identification, Natural History, Range, and Citations. Within the Citations for each species the references are clustered under the subheadings: General, Development/Morphology, Reproductive Biology, and Ecobehavior. For well-studied species, the accounts fill a page or so largely because of the extensive list of references. For lesser-known species, the accounts run a third to half a page in length.

Illustrations are included for every species that can be visually distinguished from other species. Not only are there photos of the larvae in lateral view, but also photos (and some line drawings) of key body parts, most notably the oral disc of tadpoles. Some accounts include images of the eggs and labial teeth. Habitat shots are included for a few species. All those illustrations are black-and-white, but the book also contains 12 colored plates, each showing 12 species.

Two working principles were used in developing the key to the larvae in this *Handbook*: 1) the keys are not necessarily dichotomous; and 2) to identify the taxa one has to know where

the larvae were collected. Both principles are practical realities of what one must accept to identify amphibian larvae in much of the USA, for there are simply too many taxa that have tadpoles that look alike.

The problem of keying out tadpoles has not become easier since Altig's first effort to construct a key back in 1970. If anything, identifying tadpoles has become even more challenging because many more taxa that are morphologically similar have been identified by molecular methods. Another challenging fact that has been increasingly appreciated over the last decade or two is that amphibian larvae, in particular tadpoles, have considerably more phenotypically plastic morphology than was appreciated in the past (Relyea 2001). Not a lot of attention is given to these problems in the *Handbook*, nor will I linger on them here. Rather, much like the authors, I accept them as unavoidable noise in the system.

Without a doubt my biggest criticism of this book relates to the illustrations. In trying to obtain images of the larva of every taxon, the authors searched widely, and some 70 people are acknowledged for contributing photographs to the project. But sadly most of the black and white photographs are frankly terrible. Presumably some cost constraint and/or production principle required a standardized dull gray background for all the black and white photos. The result is a multitude of dreary, blurry photographs. Collectively, the photographs take the life out of the larvae and the vigor from the volume. I fear that such washed-out images will do little to inspire folks raised in the world of endless amounts of animated color images to want to study tadpoles. It's sad that so much diligence went into this encyclopedic work yet so few of the photographs draw one's attention in a positive way.

It is odd that the authors accepted such poor quality photographs for their book considering that they provide in their *Tadpole* volume a treatise on how to take good photographs of tadpoles. Perhaps the authors were trapped by cost constraints from the publisher to accepting poor quality images. Perhaps they trapped themselves by trying to produce at a relatively low cost a single handbook that covered the larvae of all amphibians in the United States and Canada.

From the practical view of field biology, it is unlikely that many naturalists will ever need to identify tadpoles from across the continent. As such, this single volume could have been split into four or five smaller volumes that covered more restricted geographic regions, such as those identified on the landform map of the United States and Canada provided in this book. That map identifies the broad geographic regions used in the keys. The keys distinguish, for example, whether one is east or west of the Rockies, in the Mississippi Embayment, on the Southeast Coastal Plain, etc. If I were a herpetologist working in any of those regions, I think I would have been happier to buy a guide for the amphibian larvae restricted to my region. I would have been willing to pay $30 or more for the smaller handbook for my region with the understanding that the high price was used to provide high quality photographs and illustrations in the regional guide. The whole set would, of course, be priced much above the $75 that is the list price for this single massive volume. But it could then have included higher quality illustrations and photographs.

Altig and McDiarmid use throughout their *Handbook* the contemporary names for North American taxa following Frost et al. (2006). Thus we have *Lithobates*, *Anaxyrus*, and *Rhinella* rather than *Rana* and *Bufo*. I have no problem with the newer names. But I think that a Handbook as exhaustive as this would have benefited from a table giving both the old and new names. Without that in immediate reach, those new to herpetology and working with older field guides for the adult amphibians, might be slowed down a bit as they assure themselves that what older volumes call *Rana catesbeiana* is indeed *Lithobates catesbeianus*.

Given the many decades it took to compile the massive amount of information in this volume, one cannot realistically expect the co-authors to produce a second edition expanded to include, say, the table just mentioned and, more importantly, better photographs. So this raises the question of how one could build upon this volume to produce a resource that is both more inspirational and more effective as a field guide. In that regard, I hope that the authors, or others following in their footsteps, make an effort to link the book's contents to a website where additional information, particularly better images, could be posted.

The authors, in fact, have a website "Tadpoles of the United States and Canada: A Tutorial and Key" (www.pwrc.usgs.gov/tadpole/) that has many lovely color photographs and a very good primer to help neophyte herpetologists get started in keying out tadpoles. But that website is limited to anuran larvae and the taxonomy is not up to date.

One could envision, though, information in both the *Handbook* and on that website linked to a database like AmphibiaWeb (www.amphibiaweb.org). AmphibiaWeb already includes videos of live animals in the field. Having video of the larvae in the wild would be an aid not just in identifying the larvae, but for gaining a sense of the organisms' behavior and ecology. It is in that field setting, for instance, that one can tell whether a larva's color pattern is cryptic or aposematic. Such information may be accessible from the papers cited in this *Handbook*, but being able to just click on a link that immediately brings up a good video would help bring the information in the *Handbook* into the 21st century.

In truth, when many of us approach a body of water in search for amphibian larvae, we are beginning to identify those organisms before we even see them. We are attentive, for example, to the landscape that we are in, the type of vegetation in the area, how fully canopied the water bodies are; how deep, wide, still or flowing the water is. We are on the lookout for tadpole predators. We are listening for frog calls that may give us a clue as to what species are breeding now or might have bred recently at that site. We use all of that information in a gestalt fashion to predict what tadpoles we might see once we get to look in the water. In a similar way, it would be great if the factual information in this book could be embellished with all that additional information. And it certainly can be done with audio and video tracks accessible via the Internet.

To go one step further, because so much of the ability to distinguish morphologically similar taxa depends on one's location, one can imagine a smartphone app that turns the Altig and McDiarmid encyclopedic volume into a convenient field guide. Right now the book is too big and too reliant on library-based information to fill that role. But one could build that field resource for one's smartphone from information in this book. I can imagine an app that takes into consideration my GPS coordinates, the time of year, the type of aquatic body before me, and perhaps the acoustical environment around me, and then gives me a list of the amphibian larvae that most likely to be in the water before me at that time.

Bird guide apps with this sort of information have been available for some time. The *Handbook* has the core information that one would need to start to build such a useful application.

Writing this review gave me a chance to reconsider where I think tadpole taxonomy is likely to go in the next decade or two. When I consider how difficult it was to identify amphibian larvae in the field back in 1970 and realize that the problem has not gotten any easier with the proliferation of species, I have little faith that greater attention to morphological detail will resolve the problem. I'm optimistic, however, that we will be moving toward the ability to do genetic screening in the field and that will certainly be a help for biologists, who have to know for sure what species they have at hand. As noted in an essay I wrote built around the first book on tadpoles that Drs. McDiarmid and Altig co-produced, tadpoles are typically more numerous than adult anurans and often easier to find and catch (Wassersug 2000). As such, when we get to the point that we can do genetic identification of amphibians in the field, it is as likely that biologists will be getting tissue for testing from larvae as well as adults. In that regard, the app that I have envisioned above may be particularly useful in narrowing down the number of taxa to be considered at any particular site at any particular time.

In sum, this book has an historic feel to it, and, given its prodigious bibliography, can lead one back to pretty much all that is known about the natural history of North American amphibian larvae acquired over the last two-hundred years. It also can be used to build a much more powerful tool for identifying amphibian larvae in the future.

The last couple of decades have seen an increasing number of high quality guides to the amphibians and reptiles of many parts of this world. Even tadpoles, which have long lingered in comparative obscurity, have recently been the subject of comprehensive, lavishly produced guides (e.g., Channing et al. 2012; Anstis 2013; Ambrogio and Mezzadri 2014). Continuing this trend, Burkhard Thiesmeier has produced a pictorial atlas to the larval amphibians of Germany. Now, compared to other parts of the world, the German amphibian fauna can be considered well known with plenty of guides available. Even for tadpoles a dedicated guide exists that is currently in its eleventh edition (Berninghausen 2012), which leaves the question whether this new book really offers anything new. The answer to that is simple: it absolutely does!

Compared to conventional guidebooks, the pictorial atlas follows a somewhat different concept. It is not so much a standalone guide but is rather meant to supplement other guides to help identify live larvae in the field, although it should be sufficient in most cases. As such, it does not contain much traditional information, for instance labial keratodont formulae of tadpoles are not provided, and the verbal description is limited to just a couple of short paragraphs highlighting the most significant characters observed in living larvae and some pertinent information on size, distribution, or general ecology. The focus is instead on providing detailed photographs and it is here that the book excels. Altogether, more than 500 photographs of consistently very high quality depict larvae at various stages throughout their development, usually covering about ten to twelve different stages per species from hatching to the end of metamorphosis. Often multiple photographs of different specimens of the same stage and/or different views of the same individual are provided. For most species, additional pictures are provided of specimens from different localities or different habitats, which give some idea about the range of natural variation in pigment patterns etc.

The atlas covers all German amphibians, except the viviparous Alpine Salamander (*Salamandra atra*). All species are treated in separate accounts, except *Lissotriton helvetica* and *L. vulgaris*, which are very similar and easily confused. Larvae of these two species are depicted side by side and seeing them this way really highlights the subtle, but distinct, differences between them. One of my favorite illustrations is found here, a plate of sixteen rather charming portraits of larvae of different ages of both species. Some other remarkable pictures include an image of a squirming mass of freshly hatched *Rana temporaria*

tadpoles with exceptionally long external gills, making them almost look like newt larvae, or of *R. arvalis* tadpoles with rather beautiful gold flecking.

Although the book is written in German, there is little text and for these parts it is easy to understand (or to translate), and anyone with a modest command of the language should have no trouble. All covered species are more or less widespread throughout Europe, so this book should be of use not only to herpetologists working in Germany, but well beyond her borders. Furthermore, anyone with an interest in amphibians and their larvae will appreciate this book and enjoy the beautiful photographs.

When I first received a copy of *Amphibians of Ohio*, the first thing that hit me was the size of this volume. At 916 pages and a mass of over 3.5 kg, this beast certainly won't be accompanying any but the most masochistic of herpetologists in their field pack. With this massive volume, Ohio joins the ranks of states that have been producing quality publications on their native herpetofauna over the last decade that target herpetologists but can also serve the novice herp enthusiast. It has been over a quarter-century since Pfingsten and Downs published the *Salamanders of Ohio* (1989) and nearly 80 years since C. F. Walker's *Amphibians of Ohio. Part I. The Frogs and Toads* (1946). Such a complete and comprehensive guide to Ohio's amphibians has been long overdue.

This book begins with a brief Abstract, Preface, Dedications, Acknowledgements, Editors and Contributors, and a very brief description of the maps. This page also provides a very useful map of Ohio's Lake Erie Islands. As mentioned on this page, included with the volume is a pull-out map of Ohio's townships and counties. This map is also reproduced on the final four pages. The book is then broken down into 12 sections: Introduction, History of Herpetology in Ohio, the Ohio Environment, Amphibian Systematics, Salamanders, Frogs and Toads, Potential Occurrences and Exclusions, Developing Priorities for Conservation of Ohio's Amphibian Diversity, Amphibian Conservation, Ohio Amphibian Distributions, Environmental Applications, and Summary and Outlook. Following these sections are two Appendices, a Glossary, Literature Cited, and finally the Index.

The Introduction is short and comprehensive. Of greatest interest to me were the tables breaking down the exhaustive work conducted by each of the editors over the years that ultimately contributed to this volume. To produce a volume such as *Amphibians of Ohio* takes a massive amount of work and I can't recall seeing a book such as this providing detailed information on the effort put into gathering the data to produce it. I think a great many take for granted the sheer amount of work and dedication it takes to pull off something like this.

Section II reviews the history of herpetology in Ohio, which is quite storied. This includes a short synopsis of how our own international Society for the Study of Amphibians and Reptiles began as The Ohio Herpetological Society. Included as well are contacts for all of Ohio's extant herpetological societies. Given the general decline in herpetological societies over the years, it is nice to see that Ohio still has several up and running.

Section III and its six subsections describe all aspects of the environments in Ohio. These are straightforward, yet detailed enough to provide the reader with more than just the brief overview found in some guides. Section IV covers amphibian systematics. There is also an introduction to the species chapters, which make up the majority of the book.

The next two sections cover salamanders and frogs (Sections V and VI, respectively). Each section begins with a detailed discussion of each order's biology. This portion also includes a key for all species of Ohio salamanders and frogs. Section VI also includes a very detailed discussion on anuran calls. There are written descriptions of each species calls, including the various kinds of call that may be produced (advertisement, aggressive, etc.). There are even sonograms of each species' advertisement call, which is a nice detail missing from many state guides. Then the sections move into the real meat of this tome, the species chapters, of which there are 37. The authors have made every effort to make each chapter as detailed as possible. For example, the chapter on the relatively poorly known Four-toed Salamander (*Hemidactylium scutatum*) by Timothy A. Herman is over 19 pages long. Each chapter also includes a number of quality color photographs, although there are a handful that appear a bit grainy or somewhat pixelated (e.g, Fig. 33-1 C and D, Fig. 33-2, and F33-7). Thankfully, it is a small number of images and detracts little from the overall book.

Section VII includes potential occurrences and exclusions. The one potentially occurring species, the Southern Leopard Frog (*Lithobates sphenocephalus*), is discussed with the same care and within the same format as the regular species chapters. In most state guides, potentially occurring species are covered with little more than a short paragraph. The exclusions were interesting to me as I have not seen a guide that goes out of the way to point out species that do not occur in the state. However, the section makes perfect sense as all of these species live nearby in surrounding states and had been previously claimed as possibly entering Ohio.

Section VIII, titled Developing Priorities for Conservation of Ohio's Amphibian Diversity, is valuable for those wanting to know how species are ranked for research and conservation needs within a state. The methods and materials are laid out

clearly. This is followed by Section IX which discusses conservation of Ohio's amphibians and the threats faced. Section X discusses the distribution of amphibians in Ohio in a contextual way, pointing out the fact that many of the state's amphibians are at periphery of their ranges. Section XI has three subsections discussing amphibians as indicators of wetland quality and using salamanders to classify headwater streams.

Section XII rounds out the book with a summary of what lead to the creation of this book as well as comments on the future of amphibian work in Ohio. The two appendices are very useful, covering field techniques, proper documentation, and preparation of voucher specimens. Included is a photo-documentation form that can be copied and used by those in the field to turn into the Ohio Department of Natural Resources Division of Wildlife. Directions on where to send it, something that many amateur herpers are often unsure of when they make a potentially new observation, are also provided. There are also recommendations for the photo-documentation of each species. Following this are the Glossary and the Literature Cited, which is a whopping 72 pages! In my estimation, this massive reference section is almost worth the price of the book on its own.

If you work with, or have more than a passing interest in, any of the species covered in *Amphibians of Ohio* you would do well to purchase this masterpiece no matter what part of that species' range you are in. Even if you are extralimital, this is a fantastic addition to any herp library. And of course, if you are a herp enthusiast at any level residing in Ohio, this book should definitely be on your bookshelf. You are unlikely to find a better referenced or more thorough treatise on any state's amphibians. What makes *Amphibians of Ohio* even more of a triumph is that while massive and incredibly detailed, it is as accessible to the amateur field herper or naturalist as it is to the most seasoned of herpetologists. *Amphibians of Ohio* is well worth the cost and I eagerly await the upcoming sister volume on the reptiles of Ohio.

Art in Herpetology

As space and available material permit, we will occasionally publish examples of historical as well as contemporary herpetological art. We welcome the submission of historical material under the following conditions:

- The work should be copyright-free and be provided as a high-resolution digitized file (consult Herpetological Art and Illustration Coordinator or Editor for specifications).
- Accompanying text should provide information on the subject matter, artist/illustrator, and publication source. Include references as needed to appropriately attribute information from other sources.

Contemporary artists are invited to submit their own work for publication:

- Artist will retain copyright of all submitted material.
- Accompanying text should provide information about technique, media, or other information likely to be of interest, especially to other artists. Other details of interest include the source of illustration subject (e.g., scientific name, geographic origin, etc.) or the work (e.g., book publication, etc.) for which the illustration was produced.
- Artists are welcome to include contact information (e.g., email address, website location), as well as indicating whether original art or prints are available for sale or if the artist is available for commissioned work.

Material may be submitted for review to Jackson Shedd, Herpetological Art and Illustration Coordinator at jackson_shedd@sbcglobal.net.

Studies on Lizards and Tuataras in Zoos and Aquariums. Part I—Introduction, History, Families Iguanidae, Agamidae, Chamaeleonidae, and Infraorder Gekkota

People often ask, "What good are lizards?" to which we respond with "What good are people?" Such anthropocentrism is abhorrent. Lizards have as much of a place on the planet as any living creature, including humans. Indeed, they have successfully inhabited Earth for much longer than humans have – lizards will undoubtedly persist long after humans and most other mammals have gone extinct. Lizards are spectacular products of natural selection and have diversified to fill an amazing variety of ecological niches. They are extremely good "model" organisms for study, and understanding their ecology and diversity can be exceedingly informative. What we have learned about lizards is applicable to nearly every conceptual area in modern biology; indeed, in many cases development of entire fields of biology had their origins in the study of lizards. Because many lizards are quite beautiful, they are very popular as pets among herpetoculturists around the world, and some people make their living by breeding many species of lizards in captivity for resale.

Eric R. Pianka & Laurie J. Vitt,
Lizards: Windows to the Evolution of Diversity, 2003

Curator of herpetology at the New York Zoological Park, Raymond L. Ditmars in his book, *Reptiles of the World* (1933), marveled at the diversity of lizards, "Looking down upon the vast Order now engaging the student's attention, even the most passive of observers cannot refrain from expressing amazement at the array of varied forms. In a subdivision, the *Sauria*, we shall consider creatures twelve feet long, with claws as long as those of a leopard—animals strong and active enough to leap at the throat of a young gazelle, tear, dismember and devour the prey; and passing such we stop to realize that tiny, limbness and worm-like, slow-moving things, burrowing their life away deep in the ground where they need no eyes—in fact, have none—are also true lizards." (Figs. 1, 2)

In this two-part paper, I follow the organizational framework of McDiarmid et al. (2012) as a taxonomic review of extant lizard groups. Part II will appear in the next issue. Original standard and scientific names are used. To update these names, use *The Reptile Database* (Uetz and Hošek 2013) and *Standard English and Scientific Names*: *Checklist of the Standard English Common Names of Amphibians & Reptiles* (Crother 2012) if occurring in North America. A complete reference called *Grzimek's Animal Life Encyclopedia* was published on all reptiles in 2003, with chapters written by experts in herpetology (Hutchins et al. 2003). Some lizard families have been only superficially investigated in zoos: Anguidae, Agamidae, Dibamidae, Amphisbaenidae, Bipedidae, Rhineuridae, Trogonophidae, Lacertidae, Gymnophthalmidae, Teiidae, Cordylidae, and Xantusiidae.

History

In May 1849, the London Zoo, founded in 1828, opened the first zoo reptile building in the world, a modified carnivorous mammal facility which used the dens as enclosures for lizards and other reptiles (Keeling 1992). The second zoo reptile building at London, designed and constructed specifically for reptiles, was opened in August 1883 (Guillery 1993) and is currently a

tropical bird building today. The newest London Reptile House was designed by curator Joan Beauchamp Procter in 1926–1927 and is still in use. The building included a center island to house venomous snakes and other potentially dangerous reptiles and a "Reptiliary" housing iguanas. New zoo design features were incorporated: differential heating, "Aquarium principle lighting" (illuminating enclosures from above), elaborate naturalistic displays, and better visitor traffic.

Philip Lutley Sclater, Secretary for the Society (1859–1902), compiled nine editions of an inventory ("List of the vertebrated animals now or lately living in the gardens of the Zoological Society of London") beginning in 1862. In 1872, his revised list included tuataras and many lizard taxa such as the Moloch, Bearded Dragon, mastigure (*Uromastyx*), Shingleback Skink and other skinks, several chameleons, as well as lacertids and iguanids to round out the collection. Books on the husbandry of lizards began to appear during the Victorian era in greater numbers (Murphy and McCloud 2010). For instance, A. D. Bartlett (1899) had written *Wild Animals in Captivity Being an Account of the Habits, Food, Management and Treatment of the Beasts and Birds at the 'Zoo,'* which treated the habits of lizards such as the Stump-tailed Skink, Thorny Devil, iguana, and chameleon. These books had a practical application in that private fanciers used the zoo protocols, particularly those from the London Zoo, though it must be stressed that these Victorian fanciers, mostly women, went on to develop many innovative techniques. Later, London Zoo curator E. G. Boulenger published an excellent book with many photographs called *Reptiles and Batrachians* (1914). He included many observations on lizards living in the collection.

Jon Coote (2001) speculated that many reptiles, especially lizards, arrived at the London Zoo in good condition in the nineteenth century because those responsible for transporting them were given specific instructions for their care: "Correspondents should engage some individual of the ship's company to take charge of the animals on board and guarantee him a handsome recompense on bringing them safely to their destination..." Food was also important for reptiles on the long sea journeys and correspondents were advised: "ants eggs, which are abundant in tropical climates, may be preserved in a jar, well tied down and with the addition of the Blattae or cock-roaches so generally obtainable on board in all their stages of growth, and of meal worms, which are equally abundant in the bread room …"

During that time, there was closer cooperation between zoo workers and private herpetoculturists than there is now. Until 1903, keepers at the London Zoo were able to trade or sell surplus animals to the general public and they supplied herps to amateur British herpetoculturists. Reverend Gregory Bateman (1897) purchased a pair of tuatara from the Zoo for £2.00 ($3.00) and other species were offered for sale in London. Prices were reasonable: small monitor lizards—5 shillings (38 cents US), Common Tegus—about £2.00 ($3.00), Red Tegus—£3.00 to £8.00

FIG. 3. Two of the rarest lizards in the world are shown here. Top: The Jamaican Land Iguana (*Cyclura collei*) was described by John Edward Gray as Colley's Cyclura in 1845. Illustration from *Catalogue of the specimens of lizards in the collection of the British Museum*. This species was thought to be extinct until rediscovered in 1970. It now faces another threat due to plans to alter the habitat.
BOTTOM: This male Grand Cayman Island Iguana (*Cyclura nubila lewisi*) allows itself to be groomed with a toothbrush by standing immobile as its entire body is brushed.

($4.50 to $12.00) depending upon size, Bearded Dragons—10 shillings to £1.00 (75 cents to $1.50), Green Anoles—as low as half-a-crown (16 cents), European Chameleons—3 shillings and 6 pence to 7 shillings and 6 pence (30 to 65 cents), British Common Lizards—4 to 6 pence each (6 to 9 cents).

Beginning in 1882, Johann von Fischer from Vienna began to publish a large number of papers on captive lizards: Ringed Agama (*Oplurus torquatus*), European Chameleon (*Chamaeleo vulgaris*), Cape Spiny Lizard (*Uromastix capensis auct.*), Stummelschwanz Lizard (*Trachydosaurus asper*), iguana (*Iguana tuberculata*), Cylindrical Lizard (*Gongylus ocellatus*), Pygmy Lateral Fold Lizard (*Ablepharus pannonicus*), Schleuderschwanz (*Uromastix acanthinurus*), Common Skink (*Scincus officinalis*), Spotted Lizard, *Eremias pardalis*), Worm Lizard (*Trogonophis wiegmanni*), and various lacertids. His seminal book on captive management was called *Das Terrarium, seine Bepflanzung und Bevölkerung* (1884) and includes recommendation for many mixed lizard combinations.

Stanley Smyth Flower published monographs and papers on amphibian and reptile longevities. In his 1937 publication, he mentioned that varanids and large iguanids are often kept in captivity but it is surprising that only two lizard taxa had reached twenty years in captivity—Slow-Worm (*Anguis fragilis*) for 32 years and Cunningham's Skink (*Egernia cunninghami*) for 20 years. In North American collections, Snider and Bowler (1992) listed one anguid, one cordylid, three gekkonids, four iguanids, three skincids, one varanid, and a number of helodermatids passing twenty years in captivity. Carey (1973) provided some notable longevity records for captive iguanas.

In the early twentieth century, papers on lizard husbandry and captive management began to regularly appear, written by London Zoo curators such as E. G. Boulenger (1913, 1920) and Joan Proctor (1928) and many European and New World herpetologists (see Card and Murphy 2000, Murphy 2007, 2009–2010 for descriptions). In 1955, an extraordinary four-volume set by Wilhelm Klingelhöffer named *Terrarienkunde* appeared and was THE husbandry reference book for decades in Europe. Toward the end of the century, zoo herpetologists became better at recognizing signs of reproductive and other behaviors and recording these observations in scientific journals. Many books focused on captive lizards: *Lizards in the Terrarium* (Jes 1987), a two-volume work called *Lizards* (Rogner 1997), *Encyclopedia of Terrarium* (Bruins 1999), *Biology, Husbandry, and Medicine of the Green Iguana* (Jacobson 2003), *Vivarium Life* (Leutscher 1952), *Firefly Encyclopedia of the Vivarium* (Alderton 2007), *Reptiles, Amphibians, and Invertebrates* (Bartlett et al. 2001), *Handbuch der Terrarienkunder* (Stettler 1978), *Das Terrarium* (Kahl et al. 1980), two-volume *Die Terrarientiere* (Nietzke 1969, 1972), *Guide to Lizards, All about Lizards,* and *Giant Lizards* (Sprackland 1977, 1992, 2010), *Breeding Terrarium Animals* (Zimmermann 1983), *The Completely Illustrated Atlas of Reptiles and Amphibians for the Terrarium* (Obst et al. 1988), *Reptiles and Amphibians: Their Care and Behavior* (Vogel 1964), and *The Lives of Captive Reptiles* (Petzold 2008). Exciting new possibilities appeared in the literature such as investigating the evolution of social cooperation in lizards (Dickinson and Koenig 2003; Sinervo and Clobert 2003) and manipulating clutch and offspring size (Sinervo 1994). Ethologists and other researchers from the academic community began working jointly with zoo colleagues on projects in zoos and aquariums, resulting in improved studies (see Sajdak 1983; Chiszar et al. 1993; Chiszar and Smith 2005; Garrett 2005 for reviews). Reviews focusing on the nutrition of carnivorous and herbivorous lizards were published (Allen and Oftedal 1994; Baer 1994). David Crews and Leslie Garrick (1980) provided many examples for inducing lizards to reproduce in captivity. In the United States, researchers such as Gordon Burghardt, Charles Carpenter, David Chiszar, William Cooper Jr., Gary Ferguson, William Gehrmann, James Gillingham, Harry Greene, Thomas Jenssen, Hobart Smith, and Paul Weldon, were pioneers who used zoo and aquarium collections to broaden their studies. William Cooper Jr. has used zoo collections as a resource for his studies on lizard feeding behavior for many years. Examples include varanoid lizards (*Heloderma suspectum* and *Varanus exanthematicus*), geckos (*Rhacodactylus*), and skinks (*Tiliqua scincoides* and *Trachydosaurus rugosus*). Susan Barnard from Zoo Atlanta and her associates have published a number of papers on parasitism and husbandry in zoo lizards (see Murphy 2007). Backues and Ramsey (1994) performed an ovariectomy for treatment of follicular stasis in lizards. Two important overviews by Stamps (1997) and Fox et al. (2003) examined social behavior and spacing patterns in lizards.

The late Thomas Huff from Reptile Breeding Foundation in Canada identified a condition that he called "captive stagnancy." He believed that changing environmental factors was key to improving reproductive behavior and his solution was to change exhibit furniture, potential breeders, temperature, and so on to induce courtship and copulation (see Huff 1980). Warwick et al. (1995) addressed the issue of stress. Methods for egg incubation and raising neonates became more refined (see Packard and Phillips 1994). Earlier, reptile eggs were discarded in many instances because it was believed that hatching them was impossible. The importance and provision of ultraviolet light for reptiles held in indoor enclosures were highlighted in key papers by Gary Ferguson and associates (1996; Jones et al. 1996), William Gehrmann (1971, 1987, 1994), Carol Townsend (1979) and Townsend and Charles Cole (1985), and Jozsef Laszlo (Murphy 2007). Philip Regal (1980) examined temperature and light requirements. From Toledo Zoo, R. Andrew Odum (1984) stressed the importance of water quality.

Lawson et al. (2008) stressed the importance of science in zoos and aquariums. Dave Chiszar, Hobart Smith, and I argued that assessing the competence of captive-produced herps is as important as breeding the animals (Chiszar et al. 1993). We were surprised to discover that captive and wild Komodo Dragons have significantly different body temperatures (Wikramanayake et al. 1999; Walsh et al. 1999). If released into the wild, would captives with lower temperatures adjust thermoregulatory patterns upward? If deficits brought on by captivity are identified, can these be remediated? How can this be done? What necessary studies will be in place to assess survivability in the wild? These challenging issues have only been minimally addressed but there are some impressive exceptions: West Indian iguanas (*Cyclura*) serve as examples of successful field studies and reintroductions.

Family Iguanidae.—West Indian Land Iguanas (*Cyclura*) face a perilous future. Jeffrey Lemm and Allison Alberts from San Diego Zoo Global in California have worked for many years with these iguanid lizards. Their recent comprehensive book (Lemm and Alberts 2012) covers evolution and biogeography, species accounts, natural history, husbandry, nutrition, health and medical management, and conservation. The San Diego Zoo has been an integral player in iguana research and conservation over many years through publication of books and papers by Alberts and colleagues.

The Jamaican Land Iguana (*Cyclura collei*) was described by John Edward Gray as Colley's Cyclura in 1845 (Fig. 3). Four years later, one was donated to London Zoo and lived in the Zoo for 3 years, 4 months, and 29 days (Coote 2001). Concern about the iguana's future accelerated following the introduction of the Indian Mongoose on Jamaica in 1872 and things were critical by 1916 when this iguana was only found on a few small islets off the coast of Jamaica where the predaceous mongoose had not been introduced. In 1940, a total of 22 specimens were brought into captivity to try to save the species from extinction but none ever reproduced. The lizard was later thought to be extinct. A hunter's dog discovered a carcass in 1970 and a later survey located about 100 lizards left in the wild in the Hellshire Hills. There is now a headstarting program at the Hope Zoo in Kingston, which involves other zoos as well (Gibson 1993; Vogel et al. 1996). However, today there exists a sizeable threat to irrevocably develop the Hellshire Hills, the only place where the lizard is found.

The Grand Cayman Blue Iguana (*Cyclura nubila lewisi*) is one of the most critically endangered rock iguanas and Fred Burton (2000) mentioned that perhaps only a few hundred individuals

ILLUSTRATION FROM WILLIAM BEEBE'S *GALAPAGOS: WORLD'S END* (1924)

FIG. 4. Curator Perkins from San Diego Zoo moved 60 Galápagos Land Iguanas (*Conolophus subcristatus*) from Baltra Island, (known also as South Seymour Island) to North Seymour Island, which contained no iguanas in the 1940s. Had this not been done, this species would now be extinct, thanks to human activities. See text.

remained in 2000. Two years later, the population crashed precipitously and only 15–25 lizards were left. In 2003, five iguanas were hatched at the Indianapolis Zoo and two more lizards two years later. Described in 1940, the lizard was widely distributed in dry habitats over most of the island but is now restricted to a few remnant populations, due to human development, feral animals, and habitat destruction. Be sure to read Burton's *Little Blue Book* (2010) about the challenges of conserving this species. He highlights the contribution by retired National Zoo curator Dale Marcellini in developing the conservation strategy. Marcellini suggested to me on many occasions that fieldwork should always be planned in a place where one could sit on the veranda of a four-star hotel with a refreshing drink in hand and watch lizards with binoculars—Dale called this plan "Resort Research"! Another amazing field account was written by Quentin Bloxam, who nearly died while working on conserving this taxon on Grand Cayman Island (see Murphy 2007:63). Sarah Kuppert (2013) described interactive male and female head bob displays at Smithsonian National Zoological Park (SNZP). This adult male allowed itself to be groomed with a toothbrush by standing immobile to allow its entire body to be brushed. The keeper pulled off dried skin by spraying these areas beforehand with water (Fig. 3).

Noegel (1989) reproduced five species of West Indian rock iguanas (*Cyclura*) at the Life Fellowship Bird Sanctuary, Seffner, Florida. Duval and Christie (1990) outlined care for the Cuban Ground Iguana (*Cyclura n. nubila*), based on their experiences at the Indianapolis Zoo. The reproductive biology of Cuban Rock Iguanas (*C. nubila*) has been covered in detail at San Diego Zoo (Shaw 1954; Alberts 1995, 2002; Alberts et al. 1997) and Prague Zoo (Rehák and Král 1993; Rehák 1994, 1995 [1997]; Rehák and Velenský 1997, 2001). Haast (1969) hatched Rhinoceros Iguanas (*C. cornuta*) at the Miami Serpentarium and Rehák (1996)

documented the first captive breeding of the Rhinoceros Iguana in the Czech Republic. In two papers, Boylan (1984, 1985) described captive management of a population at the Taronga Zoo, Sydney, Australia and Petzold (1967) at Tierpark Berlin. Ottenwalder (1980) mentioned that Zoodom released rhino iguanas into the wild and described reproduction in captivity (Sanlley Castro and Duval 1979). Charles Knapp from the Department of Conservation at the John G. Shedd Aquarium in Chicago has published field studies on several West Indian iguanas (Knapp et al. 1999; Knapp 2000, 2001; Knapp and Malone 2003;). Duval (1982) offered suggestions for the captive management of West Indian rock iguanas. Bosch (1991) discussed ground iguanas (*Cyclura cychlura figginsi*) in the Löbbecke Museum (Dusseldorf). See also Bosch and Boscheinen (2001). Murphy (1969) described conspecific grooming behavior in this species.

C. B. "Si" Perkins, Curator of Reptiles at San Diego Zoo, and G. Allan Hancock mounted trips in 1932 and 1933 to the Galápagos Islands to study and collect animals for the Zoo (see Banning 1933 for additional information). Hancock's ship was the state-of-the-art Valero III, nearly 200 feet in length. He was a bit of a prig, insisting that his fellow passengers—a group of scientists including Perkins—dress for dinner and moreover, cease smoking and drinking. For those of us who are not focused on the latest in apparel and enjoy a bit of whisky and strong cigarettes in the evening, this trip would have been unendurable. The notation "No cocktails tonight" appeared daily in the Perkins diaries (Campbell 1978).

During the first trip, Hancock and Perkins decided to move 40 Galápagos Land Iguanas (*Conolophus subcristatus*; Fig. 4.) from Baltra Island (known also as South Seymour Island) to North Seymour Island which contained no iguanas. As Perkins wrote in his diaries, their reason: ". . . in a few years come down and see if anything has happened. A good idea, I believe." (Campbell 1978). Twenty more iguanas were translocated on the second trip.

Baltra was an American airbase during World War II in the 1940s and several thousand military and support personnel were stationed there, in part to guard the Panama Canal. Several factors contributed to the disappearance of these lizards—habitat destruction, introduction of feral animals, and using the lizards for target practice.

There appeared to be virtually no successful reproduction or recruitment on North Seymour for the subsequent 47 years so a pair of adults was brought to the Charles Darwin Research Center on Santa Cruz Island to begin a captive colony; additional iguanas were included in this potential breeding group later (Cayot et al. 1994). These iguanas reproduced and survived, particularly because feral cats and dogs had been reduced on Baltra. In June 1991, 35 five-year old iguanas were repatriated to Baltra and 24 were released the next year. This head-starting program was truly an accomplishment deserving praise, thanks to Perkins and Hancock.

Ray Pawley from Chicago Zoological Park (Brookfield Zoo) maintained a colony of Marine Iguanas (*Amblyrhynchos cristatus*) in a large exhibit in the reptile building (1965, 1966, 1969, 1971). I visited the Zoo on a number of occasions and was impressed by the overall health and activity of these lizards. This species is challenging to maintain successfully in captivity but one of his saurians lived for over six years.

Dennis Desmond told me that his adult female Green Iguana (*Iguana iguana*) would sleep with a furry toy virtually every night and the lizard often wrapped its forelimbs around this unusual object (see photo in Murphy 2007). Dedekind (1977) recorded his observations made during hatching and raising of a Green Iguana in the Berlin Tierpark (Fig. 5.). Mendelssohn (1980) provided recommendations on care, based on reproduction in a colony at Tel Aviv University in Israel. Howard (1980) bred them at the Twycross Zoo and Banks (1984) at Melbourne Zoo. Wallach (1966) described hypervitaminosis D in Green Iguanas. Bosch and Werning (1996) discussed the captive management of Green Iguanas and other iguanids. Wallach and Hoessle (1968) documented fibrous osteodystrophy in Green Iguanas. Zwart and Van de Watering (1969) described pathology and etiology of abnormal bone formation in this species. The reproductive biology of Green (*Iguana*) and Desert (*Dipsosaurus*) iguanas has received attention (Judd et al. 1976). Day et al. (2000) provided a species account of the Lesser Antillean Iguana (*Iguana delicatissima*). Bosch and Werning (1996) wrote a manual on iguana care.

Arnett (1979) reproduced the Fiji Banded Iguana (*Brachylophus fasciatus*) at Knoxville Zoo and over 100 young have been produced at San Diego Zoo (Fig. 6.). In 2008, a new species was described (*B. bulabula*) and a breeding program has been initiated by San Diego Zoo. Boylan (1989) bred the Fijian Crested Iguana (*B. vitiensis*) at Taronga Zoo in Sydney, Australia. Carpenter and Murphy (1978) noticed aggressive behavior and color change between males in the Fiji Island Iguana at Dallas Zoo.

Marcellini and Jenssen (1991) documented avoidance learning by the Curly-tailed Lizard (*Leiocephalus schreibersi*). Petzold (1962) successfully bred the Northern Curly-tailed Lizard (*Leiocephalus carinatus*) at Berlin Tierpark. Gibson and Buley (1996) described captive management and breeding of Madagascar Spiny Iguanas (*Oplurus c. cuvieri*) at Durrell Wildlife Conservation Trust. Vogel (1992) outlined care and breeding of the Serrated Casque-headed Iguana (*Laemanctus serratus*) over several generations in the Exotarium of Frankfurt Zoo. At Dallas Zoo, we received a group of lizards confiscated by U.S. Fish & Wildlife Service, which included Casque-headed Iguanas (*Laemanctus longipes*), Smooth-helmeted Iguanas (*Corytophanes cristatus*), Hernandez Smooth-helmeted Iguanas (*Corytophanes hernandesii),* Common Monkey Lizards (*Polychrus marmoratus*) (Fig. 7), and Tree Runners (*Plica plica*). All but the last taxon was kept at ca. 72°F (22°C) ambient temperature with a basking spot. A colleague told me that he found a Smooth-helmeted Iguana resting on a tree trunk in the field and did not move for over a week until a large beetle passed by. At Dallas Zoo, a group of Baja California Rock Lizards (*Petrosaurus thalassinus)* and Banded Rock Lizards (*P. mearnsi*) were displayed in a large enclosure (Fig. 8). These lizards were hardy and constantly active. Bayard Brattstrom visited and suggested that we arrange two hotspots above two platforms where these lizards would learn to shuttle back and forth between them. A timer would be used for tripping a relay switch to turn one or the other off; both would not be on simultaneously. An intriguing display showing shuttling thermoregulation (see Regal 1980:83 for another view) but we never got around to doing it.

Reproduction and behavior of the Green Crested Basilisk (*Basiliscus plumifrons*) were described by Pawley (1972) at Brookfield Zoo, Blake and Stewart (1980) at Edinburgh Zoo, Olexa (1976) at Prague Zoo, and Banks (1983) at Melbourne Zoo. Kuppert (2013) recorded head bob displays at National Zoo. Stunkard and Gandal (1966) identified a digenetic trematode, *Parahaplometroides basiliscae* from the mouth of a basilisk at New York Zoological Park. At Dallas Zoo, a mixed exhibit of Common Basilisks (*Basiliscus basiliscus*), Western Basilisks (*B. galeritus*), and Brown Basilisks (*B. vittatus*) were visible to the visitor

SMITHSONIAN INSTITUTION LIBRARIES, WASHINGTON DC

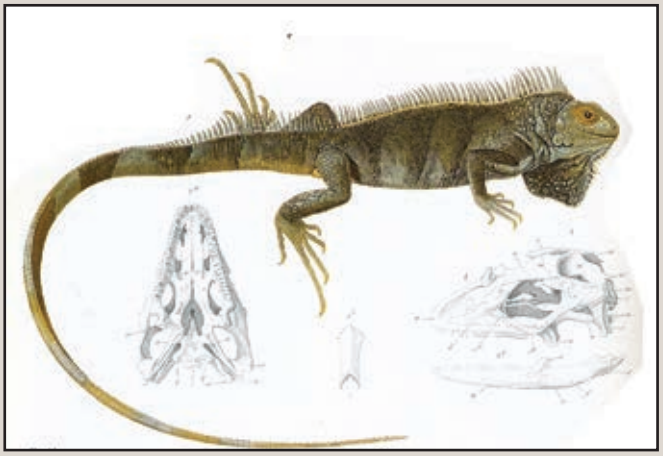

FIG. 5. Illustration of Common or Green Iguana (*Iguana iguana*) in Baron Georges Cuvier's *Le règne animal…*, published in 1836–9. An adult female slept with a furry toy virtually every night and the lizard often wrapped its forelimbs around this unusual object.

FIG. 6. The Fiji Island Iguana (*Brachylophus fasciatus*) here pictured in "Proceedings of Scientific Meetings of the London Zoological Society" is certainly impressive but it is at risk due to human factors. The San Diego Zoo is playing a significant role in developing captive assurance colonies.

SMITHSONIAN INSTITUTION LIBRARIES, WASHINGTON DC

FIG. 7. Illustration of Common Monkey Lizard (top right) (*Polychrus marmoratus*) by H. R. Schinz (1833), *Naturgeschichte und Abbildungen der Reptilien*. I saw one in the wild in Guyana and it was virtually invisible in a bush. It remained immobile when I reached for it and only moved when I grasped it.

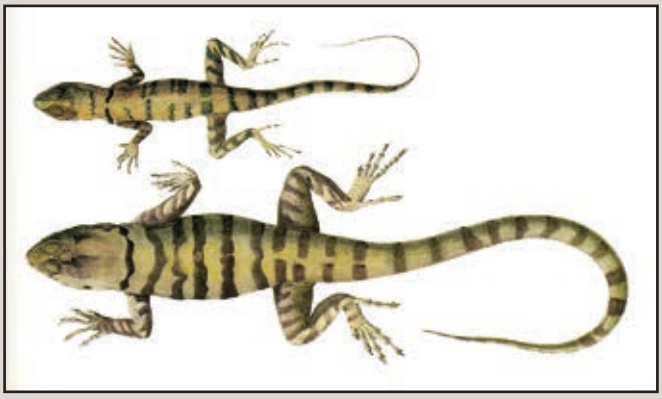

FIG. 8. Illustration of Baja California Rock Lizard (*Petrosaurus thalassinus*) and Banded Rock Lizard (*P. mearnsi*) [above] from *Nouvelles archives du Muséum d'histoire naturelle de Paris,* 1865–1908. An interesting exhibit using these lizards could be developed to show shuttling thermoregulation. See text.

FIG. 9. There are beautiful images in "Proceedings of Scientific Meetings of the London Zoological Society" between 1861–1929. An adult male Frilled Lizard (*Chlamydosaurus kingi*) from Australia flared its frill with open mouth, stood bipedally, made a series of grunts and rushed toward the keeper at Dallas Zoo. New employees found this display to be unsettling when witnessed the first time and, of course, were never forewarned by their perverse co-workers.

SMITHSONIAN INSTITUTION LIBRARIES, WASHINGTON DC

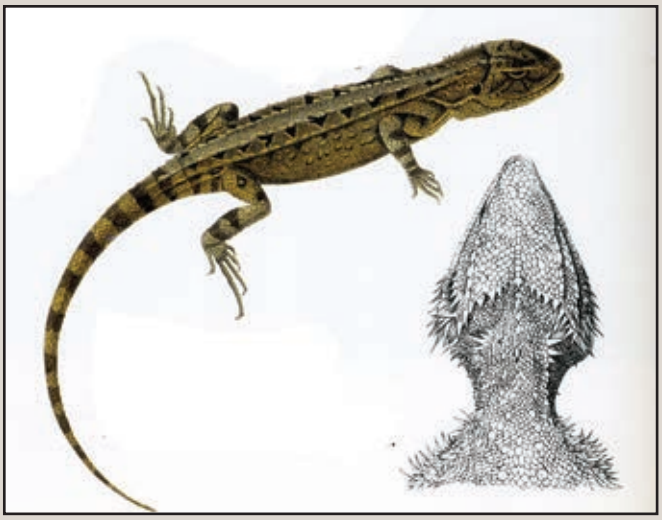

FIG. 10. Illustration of Bearded Dragon (*Pogona barbata*) in Baron Georges Cuvier's *Le règne animal…*, published in 1836–1839. This lizard is hardy in captivity and is highly variable in color.

SMITHSONIAN INSTITUTION LIBRARIES, WASHINGTON DC

FIG. 11. Illustration of Egyptian Spiny-tailed Lizard (*Uromastyx aegyptius*) in Baron Georges Cuvier's *Le règne animal…*, published in 1836–9. The Oklahoma City Zoo was successful at keeping members of this genus in large enclosures with a sandy substrate and high temperatures.

FIG. 12. A small group of Common Flying Lizards (*Draco volans*) was kept at Dallas Zoo where males regularly displayed to each other by extending dewlaps and partially extending wings, and bobbing the body. This illustration represents a different species (*D. lineatus*) but is included to show the head and body of this unique lizard. Publications of London Zoological Society between 1860–1921 had beautiful lizard illustrations such as Flying Lizards (*Draco*). To see a complete list of all amphibians and reptiles, consult *Transactions of the Zoological Society of London: an index to the artists, 1835–1936*, compiled by Nina J. Root and Bryan R. Johnson, and *Proceedings of the Zoological Society of London: an index to the artists, 1848–1900*, compiled by Nina J. Root and Bryan R. Johnson (1986).

when entering the reptile building. The enclosure was large and high; the lizards were active, climbing branches and the rock façade.

At Dallas Zoo, a number of beautiful *Sceloporus* were kept over the years: Adler's Spiny Lizard (*S. adleri*), Yarrow's Spiny Lizard (*S. jarrovii*), Mexican Emerald Spiny Lizard (*S. formosus*), Blue Spiny Lizard (*S. serrifer cyanogenys*), Crevice Swift (*S. torquatus*), Crevice Spiny Lizard (*S. poinsettii*), and Eastern Fence Lizard (*S. undulatus*). Brasfield et al. (2008) examined reproductive and thyroid hormone profiles after a period of brumation and Rich and Talent (2008) recorded the effects of prey species on food conversion efficiency and growth in the Western Fence Lizard (*S. occidentalis*). The Coachella Valley Fringe-toed Lizard (*Uma inornata*) and Colorado Desert Fringe-toed Lizard (*U. notata*) were maintained in a large outdoor exhibit with an extensive sandy area. The lizards were removed to an indoor holding area in the winter. Foster et al. (2015) maintained and reproduced the Yuman Fringe-toed Lizard (*U. rufopunctatus*) at Phoenix Zoo. In central Texas, semi-arid places with limestone ledges and slabs called Texas holey rock (popular in cichlid aquaria) have the most beautiful male Eastern Collared Lizards (*Crotaphytus collaris*) which were kept on display at Dallas Zoo. The Reticulated Collared Lizard (*C. reticulatus*) from the Rio Grande Valley in south Texas was also exhibited. Both species fed well on small lizards (*Uta, Urosaurus, Sceloporus*) and insects. I was surprised when a cage mate (*Sceloporus serrifer cyanogenys*) larger than the Eastern Collared Lizard had been killed and swallowed, later to be regurgitated after being partially digested. This predaceous saurian reminded me of a miniature *Tyrannosaurus rex*.

In 1890 and 1897, three specimens of Ditmars' Horned Lizard (*Phrynosoma ditmarsi*) were collected somewhere near the United States–Mexican border but the site was not recorded. The first lizard was deposited in the collection of the American Museum of Natural History in New York. The second and third specimens were donated to Raymond L. Ditmars who was able to observe one for about a year until it died (Ditmars 1951). Both were preserved and sent to Leonhard Stejneger at United States National Museum in Washington, DC. Stejneger described the lizard in honor of Ditmars (Stejneger 1906). No additional specimens were found alive until 1970. In a brilliant plan to discover the lizards' location, two of the preserved lizards' stomachs were examined, and insect remnants, plant fragments, and small pebbles were saved and sent to specialists for identification and a possible locale was pinpointed, based on known distributions of these animal, vegetable, and mineral clues. With this additional information, Ditmars' Horned Lizard was rediscovered. To pursue this amazing story, consult Ditmars (1951), Roth (1971, 1997), Lowe et al. (1971), Montanucci (1989), and Sherbrooke et al. (1998). Montanucci (1984, 1989) outlined breeding, captive care, and longevity of the Short-horned Lizard (*P. douglassi*) and Ditmars' Horned Lizard. In 2005, the Texas Horned Lizard (*P. cornutum*) reproduced at Fort Worth Zoo.

Lawler et al. (1994) outlined the ecological and nutritional management and Densmore et al. (1994) described a molecular approach for determining genetic variation in captive and natural populations of the Piebald Chuckwalla (*Sauromalus varius*) at Arizona-Sonora Desert Museum. Lawler and Jarchow (1986) presented a captive management plan, At Metro Toronto Zoo, Barker and Cranfield (1988/1989) identified *Schellackia* (*Lainsonia*) sp. in chuckwallas. Aucone et al. (2003) compared two artificial ultraviolet light sources used for Chuckwalla (*S. obesus*, now *S. ater*) husbandry.

Gamble et al. (1996) investigated plasma Itraconazole pharmacokinetics in spiny lizards (*Sceloporus* spp.) at Dallas Zoo. A number of spiny lizards, chuckwallas, and other southwestern U.S. desert lizards were kept in a large outdoor exhibit with a sizeable hibernaculum and rocky crevices. The herbivorous chuckwallas were fed fruits and vegetables in large metal trays, attracting a number of hymenopterans. Granite Spiny Lizards (*S. orcutti*) would congregate around the trays, carefully snatch the insects at mid-body and immediately and violently bang them against the rocks. I watched hundreds of feeding episodes and as far as I could tell, no lizard was ever stung. Keeper Mark Doles studied maternal care in this colony (Doles 1998). He asked two questions: how long would a female continue to rebury her nest if excavated and could she discriminate between her nest and another dummy hole nearby? Read his paper to answer both questions. A hint—females excavated multiple exploratory holes but abandoned all but one for oviposition.

Knight Anoles (*Anolis equestris)* at Dallas Zoo displayed to smaller anoles (*A. sagrei, A. carolinensis*) that were used as food. Instead of trying to flee from the larger lizards, the food anoles sometimes displayed head bobs, lateral compression, and dewlap extension. On rare occasions, they continued the display even while being swallowed. Rosenberg (1941) covered behavior and husbandry in *A. equestris* and *A. ricordii*. One of the most interesting anole exhibits showing their lifestyle was at Lincoln Park Zoo in Chicago during the 1950s where a large planted exhibit housed Brown and Green Anoles from Florida. This stately enclosure was remindful of a Victorian terrarium or Wardian fern case, viewable from all sides, with intricate and ornate ironwork and was the first display visible as one entered the reptile house. These lizards were very active: fighting, courting, ovipositing, hatching, and feeding. One day at Dallas Zoo, I felt a tremendous pain on my left earlobe as I was speaking on the telephone. One of my beloved employees had attached a large male *A. carolinensis* to the lobe and it insisted on hanging on for some minutes. My gentle nature toward my co-workers was seriously challenged.

In my view, the most productive zoo scientist studying iguanid lizards is Allison Alberts, Chief Conservation and Research Officer for San Diego Zoo Global. She is the co-founder and past co-chair of IUCN Iguana Specialist Group and president of International Iguana Foundation. She has studied endangered iguanas in Cuba, Costa Rica, Turks and Caicos Islands, Fiji, and also Komodo Dragons. To prove my point, consult the bibliography at the end of this paper.

Family Agamidae.—Murphy et al. (1978) observed defensive behavior in the Angle-headed Dragon (*Goniocephalus dilophus*, now *Hysilurus dilophus*) at Dallas Zoo. This spectacular adult lizard emitted a series of grunts and hissing sounds as it leaped bipedally toward an intruder. Specialized motor patterns included lateral presentation with open mouth, tongue rolled forward, gular sac expanded, sidehopping, tail lashing, and color change. An adult male Frilled Lizard (*Chlamydosaurus kingi*) from Australia flared its frill, stood bipedally, made a series of grunts and rushed toward the keeper at this Zoo (Fig. 9). In 2004, nine Javan Hump-headed Lizards (= Chameleon Forest Dragon, *Gonocephalus chamaeleontinus*) hatched at Denver Zoo.

Almandarz (1969) placed Bearded Dragon (*Amphibolurus barbatus*) eggs in a portable baby incubator and seven hatched at Lincoln Park Zoo (Fig. 10). Van Aperen (1969) bred them at the Melbourne Zoo. Sherriff (1989) outlined the maintenance and breeding of the Inland Bearded Dragon (*Pogona vitticeps*) at Edinburgh Zoo. Morley (1992) bred the Nobbi (*Amphibolurus*

ERNST MAYR LIBRARY, MUSEUM OF COMPARATIVE ZOOLOGY, HARVARD UNIVERSITY

FIG. 13. Illustration of Common Chameleon (*Chamaeleo vulgaris*, now *C. chamaeleon*) in Albert E. Brehm's *Illustrirtes Thierleben für Volk und Schule. Brehm's Illustrirtes Thierleben für Volk und Schule; bearb. von Friedrich Schödler. Mit, Abbildungen nach der Natur, ausgeführt unter leitung von R. Kretschmer. Neue Stereotypausg. Bibliographisches institut, Leipzig, 1875–1883* (Illustrated Animal Life for the People and the Schools; edited by Friedrich Schödler. With Illustrations from Nature, Made under the Direction of R. Kretschmer. New Stereotypical Edition, Bibliographic Institute, Leipzig.).

nobbi) at Adelaide Zoo. Montali et al. (1975) diagnosed dermatophilosis in Australian bearded lizards at National Zoo. Weigel (1989) maintained and bred the Superb Dragon (*Diporiphora superba*) at Australian Reptile Park, Gosford. He has also published a helpful book on the care of Australian lizards (1988).

Demeter (1981) reported on husbandry and breeding of the Chinese Water Dragon (*Physignathus cocincinus*) at National Zoo, Dedekind and Petzold (1982) bred the species in the Berlin Tierpark, and Frolov and Sanoyan (1986) in Moscow Zoo. The National Aquarium in Baltimore has a large exhibit devoted to Lesueur's Water Dragon (*Physignathus lesueurii*). Both *Hydrosaurus* and *Physignathus* should be kept in large, semi-aquatic exhibits or the lizards will likely abrade their rostrals by banging into the exhibit glass. Lederer (1931) published an early paper on ethology of the Sailfin Lizard (*Hydrosaurus amboinensis*). Visser (1984) described husbandry and reproduction of the Sailfin Lizard at Rotterdam Zoo. Mitchell (1986) reproduced the Philippine Water Dragon (*Hydrosaurus pustulatus*) at Dallas Zoo. At Dallas Zoo in the 1970s, two Sri Lankan lizards were displayed: Mountain Horned Iguana (*Ceratophora stoddartii*) and Sri Lanka Horned Agama (*C. aspera*). At the same time at Fort Worth Zoo, a spectacular adult pair of Lyre-headed Lizards (*Lyriocephalus scutatus*) was exhibited in a large planted enclosure.

In 2004, 20 Mali Spiny-tailed Lizards (*Uromastyx maliensis*) hatched at Detroit Zoological Institute. Watson (1969) outlined the care of Mastigure Lizards (*Uromastyx*) at Jersey Wildlife Preservation Trust. Wheeler (1990, 1991) described husbandry of Mastigures at Oklahoma City Zoo. Morales and Dunker (2001) found tuberculosis, *Mycobacterium marinum*, in a group of Egyptian Mastigures (*Uromastyx aegyptius*) at Steinhart Aquarium (Fig. 11). Raphael et al. (1999) evaluated vitamin D concentrations in *Uromastyx* spp. with and without radiographic evidence of dystrophic mineralization at New York Zoological Park.

Coburn (1975) described post-mortem removal and artificial hatching of Rainbow Lizard eggs (*Agama agama*) at the Cotswold Wildlife Park, Oxfordshire UK. A small group of Common Flying Lizards (*Draco volans*) was kept in a large planted exhibit at Dallas Zoo where they lived for several years (Fig. 12). Males regularly displayed to each other by extending dewlaps and partially extending wings, and bobbing the body but I never saw them lock jaws or bite each other. Some ant colonies lived in the enclosure and were intermittently picked off by the lizards.

Family Chamaeleonidae.—Most chameleons have been difficult to keep for extended periods in captivity (Fig. 13). In 1818, the Menagerie of the Imperial Cabinet (Vienna) had chameleons from North Africa and eggs were laid in 1845 but did not hatch. The menagerie received many chameleons as gifts from various sources between 1818–1851. Duméril (1854–1855) found that captive chameleons fared poorly between 1851 and 1855 at the Menagerie Jardin des Plantes, Paris for although more than 160 were kept, none lived more than 13 months. Females often died from reproductive complications—no eggs were ever hatched. See Andreone et al. (2005), Andrews (2005, 2008), Andrews and Donoghue (2004), Andrews et al. (2004), Andrews et al. (2008), Ferguson et al. (2003, 2007), Karsten et al. (2008, 2009) for recent success stories.

Johann von Fischer was the first to document copulatory behavior and reproduction in Common Chameleons (*Chamaeleo vulgaris*, now *C. chamaeleon*) in 1882 and 1884 (see Murphy 2005 for English translation; Fig. 14). He attempted to incubate nearly 800 eggs but most never hatched. The first Veiled Chameleon (*Chamaeleo calyptratus*) obtained by the London Zoo was caught in Aden, South Yemen, on 15 March 1885 and donated on 3 June 1885 by Lt.-Col. J. W. Yerbury (Coote 2001). Sarah Kuppert (2013) described color changes during courtship in this species at Smithsonian National Zoological Park (SNZP) (Fig. 15). Gary Ferguson and colleagues published a book on care of Parson's, Panther, Veiled, and Jackson's Chameleons in 2007.

At the now-defunct Belle Vue Zoo in England (see Bennett and Barnaby 1989 for this sad story), average longevity for 24 chameleons between the years 1898–1901 was slightly over three months and none survived for one year (Flower 1925). Raymond L. Ditmars had problems with chameleons which rarely survived longer than five or six months (Ditmars 1933). Flower (1925) found that chameleons rarely lived one year in captivity. An exception was the South African Dwarf Chameleon (*Bradypodion pumilum*) which have live young. In 55 years, only 15 chameleons of many species out of nearly 770 survived over one year, a rather depressing situation. By 1928, sixteen different species of chameleons had been exhibited alive in London but mortality

FIG. 14. Illustration of Common Chameleon (*Chamaeleo chamaeleon*) from John Anderson's *Zoology of Egypt Volume First. Reptilia and Batrachia* (1898). Early records show that this species was very difficult to keep in captivity.

FIG. 15. Illustration of Veiled Chameleon (*Chamaeleo calyptratus*) from John Anderson's *Zoology of Egypt Volume First. Reptilia and Batrachia* (1898). This species is very hardy in captivity.

rates were high. At the Giza Zoological Gardens in Egypt where Flower was director, 200 chameleons were maintained at the zoo between 1898–1924 but none lived for as long as four years.

See Ferguson et al. (2004) for color variation, natural history, conservation, and captive management of the Malagasy Panther Chameleon (*Furcifer pardalis*). This work included reproductive and nutritional data on five captive generations at Texas Christian University; an overall history of chameleons in captivity was included. Gary Ferguson has worked in a zoo setting for many years to investigate the captive biology of chameleons (Ferguson 1994; Ferguson et al. 1993, 1996, 2004). Early on when he brought his herpetology class to Dallas Zoo for the annual visit I asked him if he had ever seen a living chameleon. He replied no, which he said was saddening for an avid lizard ecologist. Luckily, we had a female Jackson's Chameleon (*Trioceros jacksonii*) that had recently given birth and the neonates were being maintained outside in a large screened cage. When he viewed these tiny lizards—going into I would characterize as a catatonic state, staring motionless on his haunches with no perceptible movement—I knew he was doomed. I offered some to keep in his lab in Fort Worth and he jumped at the opportunity—the rest is history!

These young Jackson's Chameleons were inaccurate at first as they tried to catch live crickets, often missing wide right or left. Occasionally, the tongue tip stuck firmly to the cage so the chameleon had to walk to the tip to reel in the tongue. The adults were kept in a large planted enclosure that covered the entire lobby of the reptile building at Dallas Zoo. Some of the trees were over 20 feet (6 m) high. When new males were first put into the enclosure, they spotted each other immediately and quickly moved toward each other to engage in male-male combat (Kommentkampf). After the struggle, the dominant chased the subdominant around the entire enclosure and eventually drove it to the very top of the highest tree. As the dominant lizard came closer, the loser released its grip, fell to the substrate, and quickly dashed away. We tested this multiple times with a series of males and the outcome was always the same; no loser suffered injuries. Females did not flee but rejected male advances by opening mouths, lateral body compression, color change, and rocking back-and-forth.

On the floor of this exhibit, a number of large *Ficus* trees were placed—each with a single chameleon—and encircled with a sheet metal barrier at the base to keep the lizards separated as these highly territorial lizards were incompatible. Daily feeding demonstrations were held and were exceedingly popular with visitors. Occasionally, sarcophagid fly larvae would be missed by the chameleons and would escape into the flower pots whereupon these insects hatched in the exhibit and were later plucked off by the lizards. One day, a fly landed on the inside of the glass at an adult human's eye level and a visitor witnessed the chameleon tongue up front and personal. She emitted a scream rivaling the decibel level of a jet plane and fell backwards into the crowd, taking a few small children to the floor with her.

Gary Ferguson, Rick Hudson from Fort Worth Zoo, and I traveled to Kenya to collect specimens for Texas zoos and preserve a series of Jackson's Chameleons for a description of what became a new taxon, now *Triceros jacksonii xantholopus* Eason, Ferguson, Hebrard 1988 (see Ferguson et al. 1991). We were hosted by Nairobi Natural History Museum, which includes a snake park. Chameleons were regularly collected as food for mambas and boomslangs living in a large pit. Jim Hebrard, then in the zoology department at University of Nairobi, kindly allowed us to stay at his apartment in the city but the space was so packed with other herpetologists—Butch Brodie, Ron Nussbaum, Tom Madsen, Ken Dodd, and a couple of other persons—that the living quarters were mindful of a homeless shelter. Gary, Rick, and I spent much time collecting on Mt. Kenya. Gary brought along some tree-climbing equipment to scale trees but the first trial was less than impressive—he ascended about six feet, lost his balance, and fell to the ground. The equipment remained unused for the rest of the trip. We hired local villagers to help collect for us but virtually all were terrified of chameleons, believing that the lizard's sharp claws were deadly poisonous. They were clearly conflicted, a few Kenyan shillings per lizard versus instantaneous death. Only one person actually held a chameleon—all of the others carried these saurians on the end of very long branches, both holding on for dear life. The villagers were stunned when we allowed these creatures to crawl on us—women screaming and children running away at full speed. One surprising and unexpected fact was the

FIG. 16. Illustration of Flying Gecko (*Ptychozoon kuhli*) from *A contribution to the zoögeography of the East Indian islands,* by Thomas Barbour (1912). At Dallas Zoo, we tested the gliding behavior but we were rather unimpressed with the outcome. The lizards did not crash to the ground when released from the top of a high ladder but the trajectory was not dramatic.

High-casqued Chameleons (*Trioceros hoehnelii*) were spaced about 3 m (10 ft) apart within juniper bushes and hedge-rows at the vet station a few miles out of town and the bongo acclimation center at the base of Mt. Kenya. Jackson's Chameleons were usually found higher in trees, especially at night, and several males might be found in the same tree. An exciting followup to our research in the 1980s was recently published by Jan Stipala. He has completed a really interesting book called *Mountain Dragons: In Search of Chameleons in the Highlands of Kenya* (2014). He has found two additional clades on the west side of Mount Kenya and at higher elevations than where we looked.

Studying chameleons in Africa is unique. One night we were using flashlights and headlamps to spot chameleons since when sleeping they become much lighter in color and stand out against the vegetation. As we walked on the trail, we could hear large mammals crashing through the bush. A Tree Hyrax suddenly emitted a call that was blood-curdling and nearly caused cardiac arrest for all of us. At that moment, we realized that this was our first field experience where we potentially could be killed and eaten by animals and so we decided to retire from collecting at night in dangerous settings. When we reached the lodge for a few drinks, elephants, cape buffalos, rhinos, wart hogs, and other mega-mammals were gathered around a pool illuminated at night for the tourists, and a leopard ran in front of our car as we left. Returning to our small hut for another well-needed drink on the patio after a starry night of chameleon stalking, a group of hyenas encircled us and they were much too close; we decided to retire earlier than planned. What was interesting was these predators were absolutely silent in their approach and we only knew of their presence when we turned on a flashlight and spotted eye-shine.

Brodie and Nussbaum were studying caecilians (*Afrocaecilia = Boulengerula taitana*) in the Taita Hills near Nairobi and suggested that we enlist the villagers to help with collecting because they were not afraid of chameleons but rather viewed these lizards as a source of income. When we arrived at the village, adults and children rushed the car and gave us a verbal price list using scientific names, reproductive condition, health, and sizes; for example, a gravid female Böhme's Two-horned Chameleon (*Kinyago boehmei*) was a steal at two Kenyan shillings. Soon, we were inundated with hundreds of herps, made our choices and purchased them, and were frantic to leave since the locals insisted that we buy all of the remaining ones. As we left the village, people ran after the car and threw more animals through the open windows on us, free of charge! Once we were out of sight, these animals were released.

The introduced Hawaiian stock of Jackson's Chameleon was definitely *Chamaeleo j. xantholophus,* the taxon described by Ferguson and colleagues. At Dallas Zoo, chameleons from this place seemed to adapt more easily to captivity when compared to the Kenyan lizards. Perhaps one reason is the daily temperature fluctuation is much less dramatic in Hawaii. It was so cold at night on Mt. Kenya, we slept in our jackets inside of heavy sleeping bags.

At San Diego Zoo, Charles Shaw recorded his observations on the reproductive biology of *Chamaeleo basiliscus* (now *C. africanus*) (Shaw 1959). Castle (1990, 1991) described husbandry and breeding of several chameleons at the Oklahoma City Zoo. Barrie et al. (1993) documented diseases of chameleons at this Zoo. Scott Stahl (1996) covered medical management.

Why do some chameleons do poorly in captivity? Here is a hint from a section in one of my earlier papers (Murphy 2009): "A new challenge is the recent study by Karsten and associates which explains why some imported animals could probably never have been successfully kept in captivity for extended periods. They found that Labord's Chameleon (*Furcifer labordi*), from arid southwestern Madagascar, is an "annual" lizard living mostly as an egg for about nine months and then only four or five months outside the egg. These lizards reach sexual maturity in two months. This may mean that the brief life span of chameleons in captivity might, for some species, actually represent the natural adult life span. So questions are asked and suggestions given by the authors in their abstract: 'Consequently, a new appraisal may be warranted concerning the viability of chameleon breeding programs, which could have special significance for

species of conservation concern. Additionally, because *F. labordi* is closely related to other perennial species, this chameleon group may prove also to be especially well suited for comparative studies that focus on life history evolution and the ecological, genetic, and/or hormonal determinants of aging, longevity, and senescence.' Flower's statement about chameleons being short-lived reptiles written over 80 years ago was prophetic."

Final thought: When Gary Ferguson and I traveled to Madagascar to do research for our books (2004, 2007), we spent one evening looking at a list of all chameleons in the country in order to predict the likely future for all of them. This was not a detailed scientific study but rather based on our observations in the field, discussions with colleagues, and literature. We concluded, much to our horror, that probably two-thirds were at serious risk of extinction and these were mostly taxa that lived in primary forest or fragile areas modified by humans. Weedy species such as the Panther Chameleons were common even in places with high human densities so they may well provide a starting point for a new chameleon radiation.

Infraorder Gekkota.—Dale Marcellini from National Zoo published several papers on acoustics, vocal and visual displays of geckos (1977, 1978). Demeter and Marcellini (1981) recorded courtship and aggressive behavior of the Streak Lizard (*Gonatodes vittatus*) at National Zoo. Heinrich Dathe (1942) recorded the birth of a Panther or Tokay Gecko (*Gecko gecko*) at Leipzig Zoo, Brodský (1969) at Prague Zoo, and Petzold (1963) bred this species at Berlin Tierpark. I witnessed a Tokay Gecko's biting power in person as I watched the San Antonio Zoo's curator pick one up whereupon it turned and bit him on the finger. The pressure was so great, the lizard's eyes sank into their orbits. It held on for one hour and nothing was successful at dislodging it, including holding it under water, until it released my colleague, probably from boredom. Frolow (1981, 1987) outlined reproduction of the Skink Gecko (*Teratoscincus scincus*) in Moscow Zoo. As part of initial keeper training at Dallas Zoo, new employees were told to clean this gecko's enclosure and the impressive defensive display was startling to all—we were accused of being sadists. Benefield et al. (1981) propagated Western Banded Geckos (*Coleonyx variegatus*) at Tulsa Zoo. From the Houston Zoo, Neitman (1983) described captive husbandry of the tuberculate geckos of the genus *Coleonyx*. Risley (1989) observed breeding of the Namib Gecko (*Chondrodactylus angulifer*) at London Zoo. Astreiko and Popovskaya (1999) from Tula Exotarium in Russia investigated the potential of breeding and raising the African Fat-tailed Gecko (*Hemitheconyx caudicinctus*) under laboratory conditions. At Dallas Zoo, we kept the Namib Sand Gecko (*Pachydactylus rangei*) and a group of Flying Geckos (*Ptychozoon kuhli*; Fig. 16). Both taxa did well in captivity. We also maintained several Cayman Island geckos with the strange standard name of Woodslave (*Aristelliger praesignis*) in the family Sphaerodactylidae. We displayed the lovely Marbled Bow-fingered Gecko (*Cyrtodactylus marmoratus*) from Peinsular Malaysia, Marbled Velvet Gecko (*Oedura marmorata*) from Australia, and Walberg's Gecko (*Homopholis walbergii*) from Africa.

Several papers on the long-term Madagascar Giant Day Gecko (*Phelsuma madagascariensis*) colony at National Zoo have been published by Béla Demeter and colleagues (1976, 1994). Bloxam and Townson (1980), Bloxam and Vokins (1978), Langebaek (1979), Wheler and Fa (1995) and Cooper et al. (1998) described breeding, research, and medical management at Jersey Wildlife Preservation Trust with the endangered Round Island Gecko (*P. guentheri*), the largest species in the genus. Howard

Fig. 17. Illustration of Common Flat-tailed Gecko (*Uroplatus fimbriatus*) [above] and Mountain Horned Lizard (*Phyrnosoma orbiculare*) from *Histoire naturelle de Lacépède. Nouvelle Édition par Cuvier* in 1841. Many of the gekkonid species in Madagascar are at serious risk of extinction due to human causes.

(1980) bred the Flat-tailed Day Gecko (*P. laticauda*) at Twycross Zoo. Rundquist (1980) reproduced Koch's Day Gecko (*P. madagascariensis kochi*) at Oklahoma City Zoo. Malagasy Flat-tailed Geckos (*P. serraticauda*) reproduced at Central Park Zoo in New York in 2003. In 2005, the endangered Yellow-throated Day Gecko (*P. flavigularis*) hatched at Wildlife Conservation Society. Linnetz et al. (1996) found gout in Giant Day Geckos. The late Sean McKeown from Fresno Zoo published many studies on Malagasy and Indian Ocean geckos (1982, 1984, 1985, 1989, 1992, 1994; McKeown and Miller 1984). Tytle (1994) presented an overview of the genus *Phelsuma*. Scott Pfaff and Sean Foley have developed an impressive program at Riverbanks Zoo, Columbia, South Carolina, breeding many species of the endangered group of flat-tailed geckos (*Uroplatus*) from Madagascar (Fig. 17). One realized goal of this initiative is the distribution of many lizards to various zoos.

Leopard Geckos (*Eublepharis macularius*) are so prolific in captivity, one could consider them a laboratory animal (see Thorogood and Whimster 1979; de Vosjoli et al. 2005). Author Philippe de Vosjoli considers this species to be the first domesticated lizard, like goldfish and parakeets. An array of color and

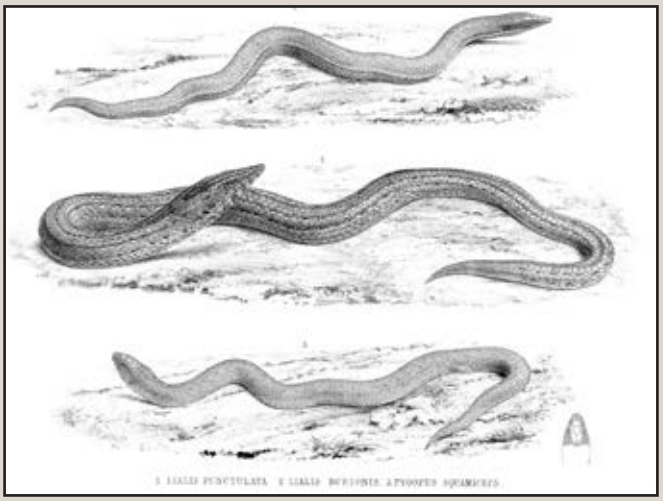

FIG. 18. Illustration of Burton's Legless Lizard (*Lialis burtonis*) in *The Lizards of Australia and New Zealand* by John Edward Gray in 1867. This lizard suffocates lizard prey by encircling the thoracic region with its flexible jaws. It is an extremely variable species.

pattern morphs are now available on dealers' pricelists—a pair of amelanotic lizards was being offered for US $1000 each. Ernie Wagner from Seattle Zoo wrote an interesting and important paper in 1980 showing skewed sex ratios based on egg incubation temperatures. See also his other papers (1974, 1979).

Kaverkin et al. (1994) described husbandry and reproduction of a eublepharid gecko, *Goniurosaurus kuroiwae splendens*, at Moscow Zoo. We kept the African Fat-tailed Gecko in the late 1960s at Dallas Zoo, which has now become a staple with herpetoculturists. One of the most spectacular eublepharids at Dallas Zoo was the Cat Gecko (*Aeluroscalabotes felinus*). A small group was kept in a cool room ca. 72°F (22°C) ambient temperature with a damp paper towel substrate. These lizards were very secretive and could not be placed on exhibit. As they grew, they all regularly pulled off skin with their mouths and swallowed it.

Some of the rarest geckos in zoo collections are any of the eight species of the genus *Naultinus* from New Zealand. There was a colony of eleven male and ten female Green Tree Geckos (*N. elegans*) at the National Zoo maintained by Béla Demeter and colleagues. These geckos were wild-caught and sent by Auckland Zoo in 1985. All of these smallish lizards in the genus are spectacularly colored and relatively easy to maintain in captivity, much like day geckos. All of the *Naultinus* survived over a minimum of several years. The National Zoo specimens were kept as groups of four in cages measuring ca. 3 ft × 3 × 2 h (1 m × 1 m × 0.6 m) with an ambient temperature of 72°F (22°C) and a small lamp provided as a thermal gradient. No courtship was observed so the lizards were watched throughout the night for two consecutive days to see if things improved—they did not and no reproduction occurred. Many examples are pictured in Sharell (1966).

One of my most exciting experiences was seeing the New Caledonian Giant Gecko (*Rhacodactylus leachianus*) at the Zürich Zoo for the first time in 1969. Curator René Honegger pulled a huge tame one from its enclosure and it rested quietly on his arm. I was truly thunderstruck. I vowed that we must have this species in Dallas so when a pair became available from a dealer for a princely sum, we jumped at the chance. I called gecko expert and Villanova University professor Aaron Bauer and asked for recommendations as to how to maintain this taxon successfully. He provided relevant environmental data and suggested cage furniture such as vertical tree limbs for a large display. Soon the geckos began to lay eggs, which we incubated at ca. 80°F (26°C). At least 60 hatched but all were males, suggesting Temperature Dependent Sex Determination. The adults vocalized when threatened, a deep guttural croaking noise. I long to see a living example of the world's largest gecko, named Kawekaweau (*Hoplodactylus delcourti*) of Maori legend, the presumably extinct giant from New Zealand (Bauer and Russell 1986). The type specimen was found in the basement of the Marseille Museum of Natural History, unlabeled and likely there for over a century. What was intriguing was this lizard was 54% larger than *R. leachianus*—about two feet long and thick as a man's wrist. What an awesome display that creature would make! I tried to convince my bosses to fund a collecting trip to try and find this gecko but I was summarily dismissed as a lunatic, who had taken complete leave of his senses.

At Dallas Zoo, we kept two pygopodids: Burton's Legless Lizard (*Lialis burtonis*) and Common Scaly-foot (*Pygopus lepidopodus*) (Fig. 18). We fed anoles, geckos, and skinks to the *Lialis* and I was constantly amazed by the cranial kinesis that allowed the jaws to wrap around the prey in the thoracic region to prevent breathing—this flexibility was very efficient in causing death. Banks et al. (1999) managed and bred the Striped Legless Lizard (*Delma impar*) at Melbourne Zoo.

Mating Gila Monsters
by Randall D. Babb — Color pencil on illustration board 15" x 10"

An air of mystique has always surrounded the Gila Monster. Its very name, *Heloderma suspectum*, is a reflection of this. The specific epithet is an artifact of the uncertainty of its venomous nature when first described: it was "suspected" to be venomous. Remarkably this debate still lives among a surprising portion of southwestern U.S. residents who believe it is bad oral hygiene that gives the Gila Monster's bite its punch. Venom is produced in a four-lobed gland located in the lower jaw and transmitted into the mouth via ducts that open into a groove between the gums and lip. Venom is "stabbed" into wounds by the teeth, which are grooved to facilitate its transmission. Bites are notoriously painful but seldom, if ever, fatal. Gila Monsters are quite common through much of their range in northwestern Mexico and the adjacent southwestern U.S., though secretive and seldom seen. They were the first venomous reptile in the United States to gain protection due to fears of over exploitation and are protected everywhere they occur. This illustration by Randall D. Babb, which appeared in *Biology of Gila Monsters and Beaded Lizards* by Daniel Beck (2005. University of California Press, Berkeley, California. 211 pp.), depicts Gila Monsters copulating in an underground retreat.

Randy Babb is a native of Arizona and works for the Arizona Game and Fish Department. His interests are broad. Along with herpetological topics his research has included opossums, porcupines, elf owls, masked bobwhite, and most recently the ecology of antelope jackrabbits. Since 2006 he, along with a team of U.S. and Vietnamese biologists, has been participating in surveying herpetofauna and bats at various localities in Vietnam. Several new distributional records and a few new species have resulted from their efforts. In addition to his work in the southwestern United States, Babb has also worked on various studies and projects in the southeastern U.S., Mexico, Central America, Namibia, Zimbabwe, and South Africa, often assisting other biologists with their research.

Babb does not consider himself to be an artist but does enjoy photography and working in color pencil, ink, and watercolors. He often takes time to illustrate specimens captured during field work while overseas, but finds that time constraints make this nearly impossible at home. His work can be found in pamphlets, on t-shirts, and in numerous books including *Venomous Reptiles of Arizona, Biology of Gila Monsters and Beaded Lizards, Amphibians and Reptiles in Arizona, Deer of the Southwest, Lizards of the American Southwest, Vampiro: Vampire Bat In Fact & Fantasy, Inland Fishes of the Greater Southwest: Chronicle of a Vanishing Biota, What's that Snake; a Starter's Guide to the Snakes of South Africa, Traveler's Wildlife Guide series; Southern Africa, Natural History of the Sonoran Desert*, and even on an old cover of *Herpetological Review*.

ABOUT OUR COVER: *Spinomantis aglevei*

Madagascar, often referred to as the "eighth continent," harbors a remarkable fauna notable for extraordinary levels of endemism. For example, 100% of the native species of frogs occur nowhere else (Brown et al. 2014. Nat. Commun. 5:5046; doi: 10.1038/ncomms6046), and the rate of discovery of new species shows no signs of decline. The island's large size, complex topography, and long period of isolation have promoted extensive diversification of amphibian and reptile lineages.

Among the anurans, *Spinomantis aglevei* (Mantellidae) inhabits primary mid and low-elevation rainforest along the eastern slopes of Madagascar (Glaw and Vences 2007. A Fieldguide to the Amphibians and Reptiles of Madagascar. Third edition. Vences & Glaw Verlag, Cologne. 496 pp.). Although individual frogs are easily heard calling among the nocturnal cacophony, they are extremely difficult to see on their overhead perches along forest streams and swamps (Nussbaum and Vallan 2008. The IUCN Red List of Threatened Species. Version 2015.2. <www.iucnredlist.org>, accessed 26 Oct 2014).

Like many of the amphibians and reptiles inhabiting Madagascar, *Spinomantis aglavei* has evolved a highly advanced form of crypsis that allows it to blend in perfectly with its surroundings. Its granular skin and dermal fringes break up the outline of this arboreal frog, allowing it to disappear on the lichen-covered tree trunks and branches during the day.

Clutches of 30–38 eggs are deposited on vegetation overhanging streams. Larvae hatch and drop into the water where they complete their development (Glaw and Vences, *op. cit.*).

Like many of the denizens that rely on intact rainforest in Madagascar, this and many other species are threatened by deforestation, agricultural conversion, and increased habitat fragmentation. Fortunately, many of these remaining forests are now protected as national parks and community forests.

Our cover image was recorded by **Rob Schell** in the Mitsinjo Preserve near Andasibe in 2014, using a Canon EOS 5D Mark III and an EF 100mm f/2.8L Macro IS USM lens, at settings of f/11.0, 1/125 sec, and ISO 100. Illumination was provided by a Canon 580EX II master and two 320EX II slaves mounted on a RRS macro ring. Schell is a wildlife biologist based in the San Francisco Bay area of California. Through his photography, he has been able to share field experiences with colleagues and the general public.

SSAR BUSINESS

SSAR Roger Conant Grants-in-Herpetology Award Winners for 2015

An award in the amount of US $500 was made to each of the following individuals:

Conservation.— **Pamela Clarkson**, Southeastern Louisiana University, "Rehabilitation stress dynamics of incidentally caught Kemp's Ridley Sea Turtles (*Lepidochelys kempii*)." Advisor: Roldan Valverde. **Madeline Cooper**, Humboldt State University, "Examining invasive Bullfrog (*Rana* [*Lithobates*] *catesbeiana*) movement patterns on the Trinity River." Advisor: Sharyn Marks.

Education.— **Valentine Kheng**, Surya University (Indonesia), "HEAR: Hello Amphibians and Reptiles!!!"

The Andrew H. Price Field Research Grant In Herpetology.— **Samantha Rumschlag**, Miami University, "Toads in Peril? Assessing the risk of American Toad populations to an emerging infectious disease, Chytridiomycosis." Advisor: Michelle Boone. **Hannes Schraft**, San Diego State University, "Infrared prey sensing in rattlesnakes (*Crotalus* spp.)." Advisor: Rulon Clark.

Laboratory Research.— **Sean Harrington**, San Diego State University, "Constructing the pitviper tree of life." Advisor: Tod Reeder. **Alexander Novarro**, University of Maryland, "Will intraspecific variation buffer the effects of climate change in lungless salamanders? Measuring the effects of adult body size on the thermal physiology of *Plethodon cinereus* across an elevation gradient." Advisor: Karen Lips.

Travel.— **Kyle Hovey**, John Carroll University, "Alkaloid-based chemical defenses of the Strawberry Poison Frog *Oophaga pumilio*: do variable defenses provide equal protection from microbial pathogens? Advisor: Ralph Saporito. **John Phillips**, University of Tulsa, "Comparative genomics of eyes in Spelerpine Salamanders." Advisor: Ronald Bonnett.

International.— **Ivan Camilo Beltran Arevalo,** University of Los Andes (Colombia). "Autoresistance to batrachotoxin (BTX) in *Phyllobates bicolor*: a molecular and physiological approach." Advisor: Adolfo Amezquita. **Saeed Hosseinian**, Ferdowsi University of Mashhad (Iran), "Biogeography and phylogenetics of the *Paraklaudakia caucasia* species complex." Advisor: Eskandar Rastegar-Pouyani and Mansour Aliabadian.

Undergraduate Research.— **Mark Herr**, Penn State University, "Thermoregulation and predation trade-offs by gravid Timber Rattlesnakes, *Crotalus horridus*, at gestation sites." Advisor: Tracy Langkilde.

SSAR thanks Committee Chair, Joshua M. Kapfer (University of Wisconsin-Whitewater), and the following reviewers for their service: Christine Bishop (Environment Canada, Science and

Technology Branch), Rebecca Christoffel (Snake Conservation Society), Peter Lindeman (Edinboro University of Pennsylvania), Cynthia Paszkowski (University of Alberta), Marion Preest (Claremont Colleges), Steven Price (University of Kentucky), Hendrik Mueller (Institut für Spezielle Zoologie, Universität Jena), Sara Ruane (American Museum of Natural History), and Jeff Tamplin (University of Northern Iowa).

Details concerning the Roger Conant Grants-in-Herpetology program for 2016 can be found below.

Roger Conant Grants-in-Herpetology Program: Guidelines for Proposal Submission

Proposals will be accepted for the 2016 SSAR Roger Conant Grants-in-Herpetology Program starting on 15 September 2015. This program is intended to provide financial support for deserving individuals (with a primary emphasis on student researchers) or organizations involved in herpetological research, education, or conservation.

Who Can Apply?

All applicants must be students AND members of SSAR with the following exceptions:

- Those applying for the International category must be students but DO NOT have to be SSAR members.
- Those applying for the Herpetological Education category DO NOT have to be a student or SSAR member.
- Those applying for support of regional herpetological society projects DO NOT have to be SSAR members.

In keeping with the Society's goal of encouraging participation by the broadest possible community of applicants, preference may be given to individuals who might not have access to other funding sources. Applications must be submitted by individuals only (but see special considerations for education categories below).

Grant Amounts and Deadlines

Successful applicants in each of the categories listed below will receive an award in the amount of US $500. A total of 12 proposals will be selected each year through peer review, to receive funding. The deadline for submission is 15 December 2015 (see special note on membership dues below). The awards will be announced by May or early June 2016.

Grant Proposal Categories

- ***Conservation of Amphibians and Reptiles.***—Proposals should outline a conservation-oriented research project. This project may focus on species endangered or threatened at the state, national, or international level, or address research on potentially threatened habitats or species, or on introduced injurious species.
- ***Field Research in Herpetology.***—Proposals may address needs for field station fees or equipment and materials in field oriented projects, or the field work portions of broader studies. This might include in-situ behavioral studies, ecological, life history, or sexual selection studies. Survey work by individuals or regional societies may be submitted here or in TRAVEL below depending on how the funds are to be used.
- ***Laboratory Research.***—Proposals may address needs for equipment or materials in laboratory projects or laboratory portions of broader projects. This might include studies in behavior, biochemistry, molecular biology, biomechanics, or physiology.
- ***Travel.***—Proposals may address support for travel to field study sites near or far, or to utilize distant collections or facilities. If funding is sought to get from one place to another, proposals should be submitted in the TRAVEL category. Proposals normally submitted in the CONSERVATION or FIELD RESEARCH categories should be submitted here if travel funding is being sought.
- ***International.***—Proposals may address needs in any of the above five categories. The applicant must be a student, but not necessarily a SSAR member. Preference will be given to students with limited access to research funds and in countries where herpetological research has historically been under-funded. Note Regarding Eligibility in the International Category: In 2011, the SSAR Board of Directors decided that proposals in this category would only be accepted if they were submitted from institutions OUTSIDE of the United States. Proposals from students who are primarily affiliated with United States institutions are not eligible for this category.
- ***Herpetological Education.***—Proposals may address an educational project or start up support for an educational program in a zoo, museum, park, nature center, regional herpetological society, etc. The project must focus on a herpetological topic. Note: Although proposals for institutional projects are accepted, education proposals must be submitted by an individual (either sole applicant or principal contact person for the project). Applicants need not be students or SSAR member.
- ***Undergraduate Research in Herpetology.***—Proposals in this category can outline any research project focused on questions related to amphibian or reptile taxonomy, biology, ecology or conservation. Funding can be used to purchase equipment, materials, or as re-imbursement for travel to conduct research (i.e., offset the cost of gas for trips to field sites, museums to investigate specimens, etc.). Applicants must be currently seeking a Bachelor's Degree at an institution of higher learning. Applicants need not be affiliated with US institutions, and international applicants need not be SSAR members. Students that apply for this award must be working directly with a research advisor at an academic or professional institution (i.e., University, Regulatory Agency, Zoological Garden, Museum, etc.). This advisor must submit the letter of support for the student's work. This letter of support must explicitly confirm that the applicant is currently a student and has the time, ability and guidance to successfully complete the proposed project. Strong preference will be given for applicants that have limited funding from other sources.

Additional information and requirements are posted on the SSAR website at: ssarherps.org/pages/GIH.php. All proposals must be submitted electronically to kapferj@uww.edu as a single pdf file named "lastname-category.pdf" not later than 15 December 2015 to be considered (letter of support may be included with the proposal or sent separately). Exceptions to electronic submission and file format may be allowed for special cases with prior approval by SSAR-GIH Chair. Failure to meet these guidelines may result in elimination of a proposal from consideration.

Successful applicants are encouraged to submit the results of their research for publication in the *Journal of Herpetology* or *Herpetological Review*, and/or to present their findings at the annual meeting of SSAR. Submit proposals or questions regarding application procedures to: Joshua M. Kapfer, Chair, SSAR Grants in Herpetology, Department of Biological Sciences, University of Wisconsin-Whitewater, Whitewater, Wisconsin 53190, USA (e-mail: kapferj@uww.edu).

Grants-in-Herpetology Donor Information

Financial contributions by SSAR members, institutions, and other benefactors support this program significantly, and can increase the number and/or size of awards. Your tax-deductible (for US taxpayers) contribution to this program will directly benefit meritorious research and education in herpetology. Contact the SSAR Treasurer for additional information about contributing to the Grants-in-Herpetology Program. If you are employed by an organization that will match donations made to nonprofit organizations, please notify your employer that you have made a donation to the Grants-in-Herpetology Program.

SSAR would like to thank the many grant reviewers and donors that have been instrumental in the success of this committee for the last several decades. In particular, we wish to thank **Tom Beauvais** for his generous financial support of this program. We also thank **Dr. Rebecca Christoffel**, whose comments and suggestions greatly improved the guidelines for grant submissions in the Education Category.

NEWSNOTES

David J. Morafka Memorial Research Awards 2016

In honor and memory of Prof. David J. Morafka, distinguished herpetologist and authority on North American gopher tortoises, the Desert Tortoise Council, with the aid of several donors, has established a monetary award to help support research that contributes to the understanding, management and conservation of tortoises of the genus *Gopherus* in the southwestern United States and Mexico: *G. agassizii, G. morafkai, G. berlandieri*, and *G. flavomarginatus.*

Award Amount: US $2,000 to be awarded at the Desert Tortoise Council's Annual Symposium, depending on the availability of funding and an appropriate recipient.

Eligibility: Applicants must be associated with a recognized institution (e.g., university, museum, government agency, non-governmental organization) and may be graduate students, post-doctoral students, or other researchers. They must agree to present a report on the results of the research in which award funds were used at a future symposium of the Desert Tortoise Council.

Evaluation Criteria: Applications will be evaluated on the basis of the potential of the research to contribute to the biological knowledge of one or more of the above gopher tortoise species, and to their management and conservation. Important considerations are the significance and originality of the research problem, design of sampling and analysis, preliminary data supporting the feasibility of the research, and the likelihood of successful completion and publication.

Application Procedure:

1. Download and open an application form from the Desert Tortoise Council's website www.deserttortoise.org. The form is electronically interactive.

2. Provide all information requested on the application, including a description of the research project in no more than 1200 words.

3. Submit the completed application to grstewart@csupomona.edu as a pdf document.

4. Applications must be supported by the applicant's CV and three letters of recommendation, one of which must be from the applicant's research advisor, supervisor, or a knowledgeable colleague. Instruct the recommenders to submit their letters to grstewart@csupomona.edu as pdf documents.

5. All application materials and letters of recommendation must be received by **1 December 2015**. They will be evaluated by a committee of gopher tortoise biologists appointed by the Desert Tortoise Council Board of Directors.

6. The research award recipient will be notified of his/her selection by **19 January 2016** and the award will be presented at the 2016 Desert Tortoise Council Symposium, 19–21 February 2016.

Reptile Database Update

As of 12 August 2015, the Reptile Database (http://www.reptile-database.org) now contains 10,269 species, an increase of 91 species from the previous update in March 2015, including 72 new species described in 2015 and another 19 revalidated or elevated from subspecies status. There are now 37,093 references, including 761 published this year and an increase of 815 since March.

Selected Taxonomic News and Changes

2014 was hottest year in history.—As with climate change, the last 10 years were the hottest in history, but especially in reptile taxonomy. Every year in the past decade had at least a 100 new

species described, a number that was reached only five times before 2005 (namely in 1758 with Linnaeus himself, then in 1854, 1863, 1864, and 1887). It turns out that a record 180 species were described in 2014.

New checklists.—We have updated several species lists based on recently published checklists, e.g., those for chameleons and *Phelsuma* geckos (after Glaw and Rösler 2015. Vertebrate Zoology 65[2]:247–283), lizards of the Amazon (Ribeiro-Júnior 2015a,b), lizards of Togo (Segniagbeto et al. 2015. Zoosystema 37[2]:381–402), lizards of the Mexican states of Jalisco (multiple sources), Morelos, Hidalgo (Lemos-Espinal and Smith 2015. Check List 11[3]:doi: 10.15560/11.3.1642), and Oaxaca (Mata-Silva et al. 2015. Mesoamerican Herpetology 2[1]:6–62, and pythons (Barker et al. 2015. Zoological Journal of the Linnean Society 175[1]:1–19; doi: 10.1111/zoj.12267).

Herpetological bibliography of Europe.—The Field Herpetology special interest group of the German Herpetological Society (DGHT) has released an illustrated Herpetological bibliography of Europe that features almost 900 illustrations of European herps (in German). Access the bibliography here: http://www.feldherpetologie.de/herpetologische-bibliographie-europas/.

Wildsumaco Biological Station

Wildsumaco Biological Station is now open for use. The station is located in the Napo Province of Ecuador on the south flank of the Sumaco Volcano at about 1450 m asl on the eastern slope of the Andes. This equatorial field station can sleep 18 people and has 2.5 bathrooms, a common area for lecturing, and a kitchen. The station is a joint initiative of Francis Marion University and the University of North Carolina at Wilmington and is operated by the Wildsumaco Lodge. The lodge is a popular birding destination and is located about 0.5 km from the field station. A diverse herpetofauna is being documented at this premontane forest site. Numerous trails are available for both teaching and research that traverse elevations of 1300–1500 m in both primary and secondary forest. The property lies within the Gran Sumaco Biosphere Reserve, near Sumaco National Park. Reservation information can be found on the web site at wildsumacobio.org and there is also a Facebook page.

Slowinski Award Winner Announced

The Center for North American Herpetology has announced that the winner of the Joseph B. Slowinski Award for Excellence in Snake Systematics for 2015 is Paola A. Carrasco. Paola is affiliated with the Universidad Nacional de Córdoba, Argentina, and is recognized based on publication of the following paper: Morphology, phylogeny and taxonomy of South American bothropoid pitvipers (Serpentes, Viperidae). 2012. Zoologica Scripta 41:109–124. The paper was co-authored with Camilo I. Mattoni, Gerrardo C. Leynaud, and Gustavo J. Scrocchi.

Amphibian Disease: *Bsal* North America Call to Action

Issue.—A new amphibian fungal pathogen "*Bsal*" was identified in 2013 from a wild salamander die-off in Europe. Studies show that *Bsal* kills North American salamanders. *Bsal* is not known to occur in North America currently, but pathways for its entry do exist. Interagency and international collaboration and action will be essential to prevent or reduce risk of *Bsal* introduction to the United States, Canada, and Mexico.

Background.—*Batrachochytrium salamandrivorans*, or *Bsal*, is native to Asia, and Asian salamanders carry the fungus without showing signs of disease. Asian salamanders are held in international captive collections, and are common pets; of the nearly 3 million salamanders imported to the U.S. over the past decade, >85% were Asian salamanders. First detected and identified in the Netherlands, in the last year *Bsal* has been detected in captive salamanders in the United Kingdom. This pathogen has proved to be lethal to multiple species in both captive and wild situations. It is an emerging infectious disease that is at an

PHOTO BY MARTY SILVER

Eastern Newt eft (*Notophthalmus viridescens*)

early stage of global transmission. Wildlife scientists and managers aim to contain or treat infected animals in captive situations, and preempt the pathogen's introduction to wild populations outside its Asian range.

Why we care.—North America is a global hotspot for salamander diversity, home to nearly 50% of all species. Salamanders play key ecosystem roles, as they are centrally nested in food webs and occur both in water and on land. We use salamanders as metrics of environmental change, and they are critical to biomedical research that seeks human health benefits. Numerous threats affect amphibians, and despite the potentially dramatic impacts of the *Bsal* threat, it is controllable at this time.
PARC's Disease Task Team will develop a Strategic Action Plan that will outline approaches to protect our North American natural heritage, our native species, and ecological functions, as well as ecosystem services for human goods and services that these species provide.

***Bsal* Strategic Action Plan components**
1. Identify *Bsal* entry routes into the United States, Canada, and Mexico.

2. Develop strategies to prevent the risk of *Bsal* entry to North America, and specifically its introduction into wild populations.

3. Develop continental surveillance strategies for wild and captive populations.

4. Develop and improve response and intervention strategies (containment, treatment) if *Bsal* is detected.

5. Identify education and outreach strategies to enhance public awareness and biosecurity compliance.

Charles W. Painter Grants in Herpetology

The Chiricahua Desert Museum (CDM) has announced the establishment of the Charles W. Painter Grants in Herpetology, to support research and education on the herpetofauna of New Mexico. Charlie Painter (1949–2015) was a well-known, respected, and beloved expert on the reptiles and amphibians of the southwestern United States. Professionally, he is perhaps best remembered for serving as the first State Herpetologist for New Mexico, where he worked for over 25 years. He was a co-author of the 1996 book *Amphibians and Reptiles of New Mexico*, the definitive resource for the herpetofauna of that state. He served for many years as a section editor for *Herpetological Review*, and in 2013 was the recipient of the Alison Haskell Award from Partners in Amphibian and Reptile Conservation.

The deadline for applications is 1 November 2015. For details of this new grant program and to download an application, please visit: http://www.chiricahuadesertmuseum.com/#!charles-w-painter-grant/cbfy

MEETINGS

Meeting announcement information should be sent directly to the Editor (herpreview@gmail.com) well in advance of the event. We also welcome brief reports of meetings; please consult the Editor for details.

3–6 November 2015—IV Congreso Nacional Sobre la Investigación y Conservación de los Anfibios y Reptiles, Villhermosa, Tabasco, Mexico. Information: aicar2015@yahoo.com and www.Facebook.com/aircar.mexico.

6–8 November 2015—42nd Annual Meeting of the Kansas Herpetological Society, Hays, Kansas, USA. Information: http://www.cnah.org/khs/meetings.aspx

19–21 February 2016—Desert Tortoise Council Symposium, Las Vegas, Nevada, USA. Information: www.deserttortoise.org.

14–17 April 2016—63rd Annual Meeting of the Southwestern Association of Naturalists, Mexico City, Mexico. Information: http://www.biosurvey.ou.edu/swan/annualm.html

23–27 May 2016—1st National Congress of Mexican Pitvipers and Ophidism, Monterrey, Nuevo León, Mexico. Information: davidlazcano@uanl.mx or congresoviperidos@gmail.com

6–10 July 2016—Joint Meeting of Ichthyologists and Herpetologists, New Orleans, Louisiana, USA.

15–21 August 2016—8th World Congress of Herpetology, Hangzhou, China. Information: http://www.wch2016hangzhou.com/

OBITUARIES

Samuel Booker McDowell, Jr. (13 Sept 1928–31 Dec 2014)
The Most Important Herpetologist You Never Knew

One of the greatest joys of life is helping others and watching from the sidelines as those you help become successful, influential, and accomplished. The irony of this satisfying joy is that it happens at a stage in life when those who set you on your own path die. The feeling of this loss is magnified by the sense that you never really managed to adequately express your gratitude for their many kindnesses and generous mentoring. As prelude, this explains the next few lines meant as appreciation, as well as a scientific and personal biographic chronicle, of my friend and advisor, Sam McDowell (Fig. 1). For these and other reasons, this account might seem an odd mix of description of a scientific career, a fascinating and complex person, and the strangeness of life in general.

PHOTO COURTESY OF EDWARD I. SAIFF

FIG. 1. Samuel Booker McDowell in the 1964 Rutgers Yearbook.

Samuel Booker McDowell, Jr. was the only child of his father and Elizabeth Valentine Dickinson McDowell. Everyone knew him as "Sam." His father was born in Kentucky and his mother was born in Birmingham, Alabama. Sam's father was a Presbyterian minister who left the church after an argument and became a book salesman for John C. Winston Company. Sam never spoke of his father in my presence. His mother waited to marry until after she finished her PhD at Columbia Teacher's College (CTC), where she taught. When I first met Sam, his mother was still alive, and retired in Trenton, New Jersey. He often mentioned plans to take the train south for a visit, although he never indicated if these visits were dreaded or anticipated.

Sam's early years were in Morningside Heights, a neighborhood of the northern part of Manhattan that included Columbia and Barnard College. While his mother was teaching at CTC, Sam attended the Horace Mann School. The motto of the school—*Magna est veritas et praevale* ("Great is truth and it prevails")—is a motto that Sam embraced. The family eventually moved to a farm in Bucks County, Pennsylvania, near the town of Lahaska. Sam's "country" education included attending the Buckingham Friends School for his primary education and the Solebury School for his secondary schooling. All these schools were and remain elite prep schools.

Sam must have been a fast learner, for he entered Columbia University a few days shy of his 16th birthday and graduated at 19 in 1947. He stayed at Columbia for his graduate work and received his PhD in 1957. The ten years between B.A. and PhD were very full, both personally and professionally.

CHARLES R. CRUMLY
Museum of Paleontology, University of California
Berkeley, California 94702, USA
e-mail: chuck.crumly@gmail.com

Sam met Rosa, his future wife, when he was the fourth for a bridge game. She was the oldest of three siblings and worked as a bookkeeper for a skirt maker in the Garment District. Her father came from Lithuania and may have been part of the Jewish Eastern European Diaspora of the late 19th and early 20th centuries. Rosa was born in Brooklyn and when she met Sam her family lived in Baldwin on Long Island. I met Rosa in the mid-1970s on my first visit to the American Museum of Natural History. Rosa suffered from arthritis, which rendered her posture bent, her knees swollen and stiff, and her hands twisted. This always gave me the impression that she was often in pain. But her beauty still radiated unabated, and I believe one of the great gifts granted to Sam was his life with her. She seemed to have Sam's number and was one of the few who could defuse one of his rants with a simple "Oh, Sam."

They were married 27 June 1952, and first lived in the Highbridge section of the Bronx, where their two children were born—Edward Drinker Cope McDowell in 1955 and Janet Anne McDowell in 1957. Ed is a now a professor of mathematics at Rhode Island College, and Janet is a graphic artist in New York City. I have never met Ed, although I feel I know something about him, because during my first trip to the AMNH, Sam and Rosa let me stay in his vacated room. They lived in a high-rise apartment building perched above the throughway leading to the George Washington Bridge in the Washington Heights neighborhood of Upper Manhattan—convenient for access to public transportation, but from my perspective at the time (a southern California beach/desert stoner) distinctly post-apocalyptic. My views of New York neighborhoods dramatically changed after I looked into average rents. I was always impressed by how much more Janet knew about art, music, culture, and baseball than I did. She seemed to have Sam's brilliance and Rosa's *joie de vive*.

Sam's eventful personal life was matched by a very productive scientific period. In 1948, his first paper was published, on the palaeognathous palate of birds (McDowell 1948). This paper was to be a part of an ambitious series devoted to the anatomy of birds. He was 20 years old, but his youthful ambition for a series of papers was never realized. Three decades later, one of Sam's distinctive letters, written on legal yellow lined paper, impressed Storrs Olson (Curator of Birds at the National Museum of Natural History) so much that Olson arranged for its publication (McDowell 1978). This letter suggests a radically different and very plausible hypothesis that might explain bird palatal homologies and lack of teeth. Alas, citations to this paper are as "rare as hen's teeth."

He next co-wrote a paper on the plastron of soft-shelled turtles with Ernest E. Williams, late Curator of Reptiles at Harvard's

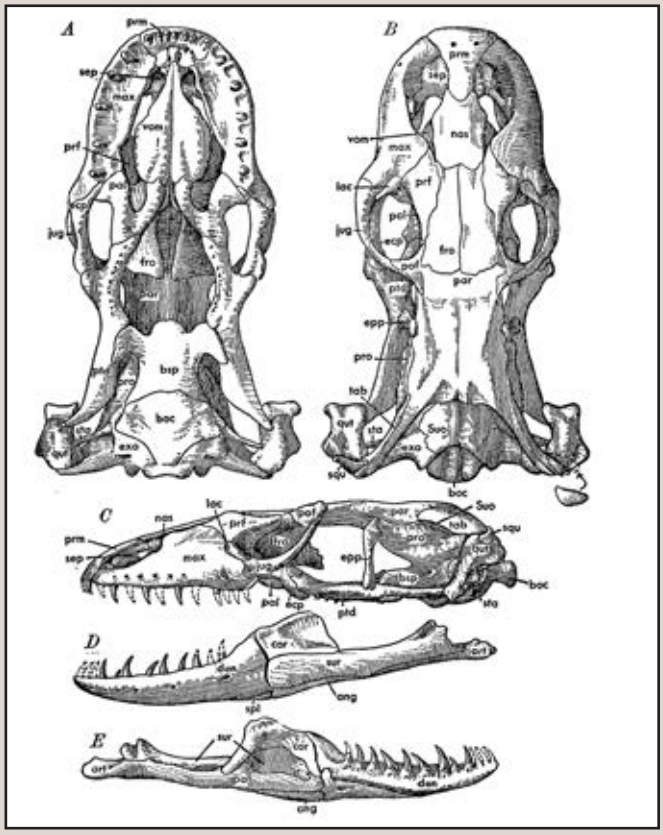

FIG. 2. This is figure 2 from Bogert and McDowell (1954) and illustrates the skull of *Lanthanotus borneensis*. At the time rare in collections, this is an example of Sam's ability to make the most of limited material. Only one example of the skull and lower jaw was examined for this monograph and it was dissected and cleaned from an MCZ preserved specimen by Sam.

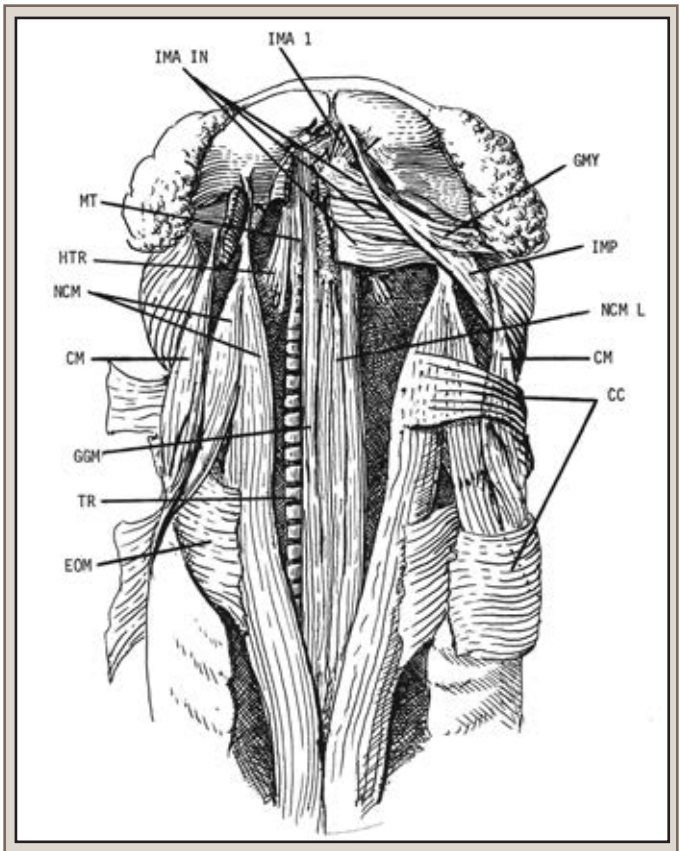

FIG. 3. This is figure 17 from McDowell's (1972) influential paper on the tongue of snakes published in a volume honoring his PhD advisor, George Gaylord Simpson. Pictured are the throat muscles of the tiny snake *Leptotyphlops humilis*. (now *Rena humilis*). Superficial muscles are illustrated on the right side and deeper muscles on the left.

Museum of Comparative Zoology (Williams and McDowell 1952). He also drafted the illustrations for Williams's PhD dissertation (1950). In later years, several other papers on turtles appeared (McDowell 1961, 1963, 1964, 1983; Hotaling et al. 1985); his papers from the 1960s are the most important and influential published on turtle systematics. Who can forget the "batagurine process"? The phylogenetic works of Gene Gaffney, Peter Meylan, Walter Joyce, myself, and many others benefited immeasurably from Sam's insights. Many of his careful anatomical observations were eventually simplified by others for the purposes of computer-based cladistic analysis.

Sam was able to use detailed descriptions of the seemingly narrow and prosaic to generate broad and influential ideas. Another of his early papers is an example of this almost preternatural skill. Along with the physiologist Charles Bogert he published on *Lanthanotus* (Bogert and McDowell 1954). At the time, this was a very rare animal, and only a handful of specimens were available among all the collections of the world. The *Lanthanotus* monograph is important. It is a detailed and in-depth review of the comparative anatomy of a lineage of squamates—the Anguinomorpha—that includes snakes. It is an example of character description and analysis that presaged and contributed data to cladistic analyses conducted decades later. And, it is explicitly comparative and phylogenetic in both execution and goals. It is a worthy successor and the equal of Camp's famous work of 30 years earlier (Camp 1923) and Underwood's influential work on snakes (Underwood 1967). The *Lanthanotus* monograph, written four years before Sam received his PhD, is a work for the ages because it is a peerless example of scholarly comparative anatomy; it should rank as one of the top ten most important papers on squamate relationships published in the 20th century. Of course, Camp's and Underwood's seminal works belong on that list and so does Estes and Pregill (1988). Filling out the top ten is a matter of opinion and likely fruitless (Beatles vs. Rolling Stones), but the *Lanthanotus* paper will be on everyone's list. All the anatomical descriptions and most of the drawings are Sam's work. His densely detailed anatomical description, characteristic of all his scientific output, is on display (Fig. 2).

In the preface to his dissertation on Antillean insectivores (McDowell 1958), Sam explained that the British paleomammalogist Percy Butler also reported some of his results independently. Sam also thanked his major PhD advisor—none other than George Gaylord Simpson. Others thanked were a "Who's Who" of 20th century luminaries in vertebrate paleontology, including Bobb Schaeffer (also on his PhD advisory committee), Glenn Jepsen, Joseph T. Gregory, Malcolm McKenna, Karl Koopman, Ernest Williams, and Bryan Patterson.

Both of these two monographs illustrate several reasons why Sam's work was relatively unsung. His writing is spare and almost painfully efficient. It is easy to spend a day on a single page of Sam's anatomical description, trying to make sure you completely understand his observations and inferences. It is also easy to become impatient because specimens need to be at hand, and often other relevant published work must be reviewed

simultaneously in order to fully grasp his intentions. The result can be in equal parts frustrating and rewarding. It took me two days, simultaneously reading DeBeer's big book on vertebrate head development, to understand his letter sent to Olson (McDowell 1978)—although maybe this says more about me than I would like to admit.

In 1957, with the birth of Janet and the completion of his PhD, Sam started at Rutgers, the State University of New Jersey. Rutgers has three campuses: the main campus in New Brunswick, and smaller campuses in Newark and Camden. Sam worked at the Newark campus, a convenient walking distance from Penn Station-Newark. Downtown Newark during most of the latter half of the 20th century could be a rough place. Imagining Sam's trip from home to campus may reveal something important about whom he was. Sam never owned a car, had a driver's license, or learned to drive—so he saved a lot of money and did his part to spare the environment. Public transportation, his life-long preferred means of travel, from Washington Heights via the A train to Penn Station, transferring to the New Jersey Transit train to Newark, followed by a 15-minute walk to campus was, and still is, a sampling of human diversity as seen through the unique lens of New York, the world's most exciting city. I took almost the same trip every time I went to Newark during my years as Sam's graduate student. It was an education for me; Sam took that trip for 38 years before retiring in 1995 as Professor Emeritus.

During most of the 1960s, Sam's scholarly output was modest. He had a new family and a relatively new job; both may have required much of his time. Also, his research focus changed—he became interested in snakes. His first snake paper was a review of Malnate's book on *Natrix* (McDowell 1961). His commentary on the persistent problems of lumping and splitting anticipated a give-and-take that persists to this day: "Theorists in taxonomy … have drawn much attention to the villainy inherent in splitting, but have said little about the dereliction of the taxonomist's duty implicit in a very large genus. As a result, almost any paper proposing to lump genera is accepted and cheered, but any proposed splitting of a genus meets with hostile suspicion and the assumption that the author must wear spats and a celluloid collar." With the advent of abundant molecular evidence supporting the identification of myriad independent lineages, would Sam be surprised that spats and celluloid collars are in fashion once more?

The humor of this quote reveals a part of Sam's life not widely known: from April 1962 to November 1963, Sam wrote for *The New Yorker*. His uncredited columns appeared in the *Talk of the Town* section at the front of each issue. They are funny, pithy, teasing of pretention, self-deprecating, and loaded with an ironic sense of humor that only a few of us were lucky enough to appreciate. His initial contribution was on the first *Latimeria* received by the AMNH. He noted that the transit from the airport to the museum took three hours: "… an indication that living fossils fare no better than anyone else in getting from the airport to midtown Manhattan." In his account of this arrival, Sam mentions Donn Rosen, Bobb Schaeffer, Ned Colbert, James Oliver, Richard Zweifel, Marjorie Courtney-Latimer, J. L. B. Smith, and a few others on slightly more than one magazine page. This was a lot of name-dropping, especially for Sam. His next column, in May, began with noting the unfortunate case of Enos, the first chimpanzee in space. Apparently, through some sort of NASA mistake, a mild shock, meant to keep Enos pulling a lever to confirm the continuation of his life, was issued whether the correct or incorrect lever was pulled. Sam used the torturing of poor Enos to complain of other evil forms of technology: "… a demented or simply spiteful coffee-vending machine … rejecting a first rate dime for a cup of third rate coffee." What would Sam have thought of a mocha decaf double-shot non-fat latte with a shot of hazelnut—all for only $5.00? Included in Sam's anti-automation rant were complaints of inadequately grounded phone booths (what's a phone booth?), self-service elevators (are there any other kind?), and automated long distance calling (alas, still with us). In February 1963, he continued his dislike of technology. Automated postage cancellation machines unable to handle the return of bottle caps (who remembers why these needed to be returned?) were singled out: "The machine has taken on the role of infallible arbiter of right and wrong that was formerly filled by the dog." Electric typewriters needed scolding for failing to impart the Anger intended by the typist in the depression of the letter "A." An automated pitching machine throwing only fastballs deserved rebuke—"Is it because they lack the guts to go to the curve with a three ball count?"

During his time as a *New Yorker* humorist, Sam became friends with A. J. Liebling, a journalist and frequent contributor to the magazine. In a brilliant Liebling piece (*The New Yorker*, Oct. 27th, 1962) about bouillabaisse, Sam is a hero: "It is a mistake to mention anything unclear to McDowell, because he will go to entirely extravagant lengths to clarify it." Liebling quotes heavily and revealingly from Sam's letters. For example, in a letter thanking Liebling for a fine lunch Sam needed to explain:

> "I want to … apologize for the peculiar way I squirmed in my chair and bulged my eyes whenever a busboy cleared a nearby table. Because of years of exposure to tobacco smoke and formaldehyde preservative, my taste buds are in no condition to make me a judge of the delicacies of fine cookery, but I am a connoisseur of fine fishbones. The sight of that menu, with its marvelous variety of fishes, immediately suggested to me what delights in fishbones there must be in the kitchen garbage cans. I could visualize a huge can of codfish skulls, with striking enlarged intercalary bones; Spanish-mackerel vertebral columns, with articulating processes designed with fine precision and economy; and the skull of my own red snapper, with magnificent supraoccipital crest. Through the years, I have learned not to follow the busboy out into the kitchen and rummage through the garbage, but desire still comes over me, and I am not quite myself when the seductive hints of fishbone-connoisseur's paradise pass before my eyes …"

There may be a link between Sam's complaints of the pitfalls and idiocy of technology and the letters he wrote. They were always hand-written, never on a typewriter. As far as I know, Sam didn't use a typewriter, electric or manual. And I don't think he ever owned a computer or had an email address. At home, he wrote his papers and letters on lined yellow legal pads, sitting in a recliner with his feet on an ottoman. He always wrote using a rapidograph India ink pen and almost never edited or scratched out what was written. None of the letters he wrote to me ever included insertions, strikeouts, or deletions.

From the late 1960s until his last paper published in 2008, most of Sam's scholarly output was devoted to snakes. His work had an effect on almost anyone with serious interests in snake anatomy and evolution. Any snake expert who has not read about the architecture of the corner of the mouth of colubrids

PHOTO BY BRANDON STANTON

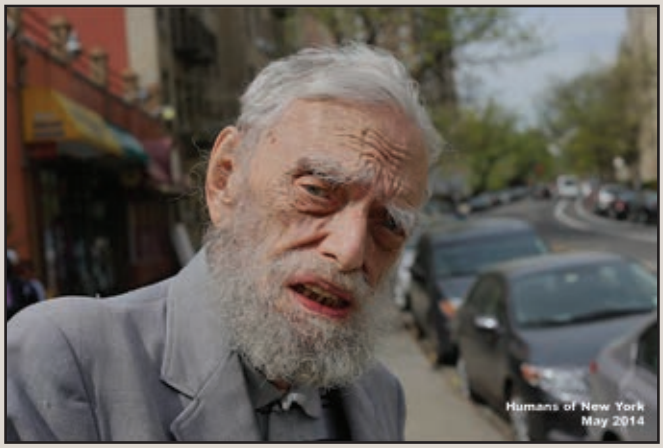

Fig. 4. Samuel Booker McDowell, Jr.—a photo from the *Humans of New York* project taken 8 May 2014. http://www.humansofnewyork.com/post/85118270706/ive-taken-over-five-thousand-portraits-of-people

should be ashamed. He was especially proud of his last paper, which was devoted to the skull of snakes (McDowell 2008, but probably written years earlier)—over 150 pages of dense anatomical description.

In 1973, Sam took a break from snakes and published a series of four papers devoted to the Heteromi. These papers appeared in volume 6 of the monumental *Fishes of the North Atlantic* (Memoir, Sears Foundation for Marine Research, Number 1, Fishes of the Western North Atlantic, part 6). Sam's 228 folio-size pages appeared just before Donn Rosen's cypriniform chapter.

As a comparative anatomist, Sam is certainly best known for his work on snakes. This work has always been difficult because all of the typical anatomy of squamates is crammed into a sometimes pencil thin (or even pencil-lead thin) snake body. Sam's large hands would not have seemed able to tease apart such diminutive detail. And yet his observations and the illustrations he drafted are detailed and beautiful (e.g., see Fig. 3, his illustration of the throat muscles of a tiny *Leptotyphlops*). Many of the skulls illustrated in his work were meticulously—almost miraculously—dissected from preserved specimens. He was often in unexplored territory and his observations were the foundation for the research of others such as David Cundall, Fran Irish, and Alan Savitzky, to mention just a few. The titles of many of Sam's papers were obscure and gave scant clues of the importance of the content. For example, the Bishop Museum series (McDowell 1974, 1975, 1979) dealt with most of the basal lineages of snakes and represents an extraordinary source of anatomical insight. Sam's work is widely regarded as perceptive; even some of his more unlikely systematic conclusions and outrageous ideas of homology have been confirmed by his astonished successors. For example, in 1968, Sam revealed that two "*Elaps*" (the type genus of Elapidae), were not even elapids, and today these two species are *Homoroselaps*. Thus, in a modestly titled paper on two misclassified snakes, Sam redefined the Elapidae and suggested relationships among African burrowing colubrids and atractaspids which have since been corroborated by molecular data (McDowell 1968).

Sam never made it easy on his readers. He had a visceral abhorrence of over-simplification and felt that anatomy for its own sake was worthwhile. He rejected the "least publishable unit" and often buried important observations and hypotheses in larger works. For example, Sam suggested that *Ramphotyphlops bramina* might be the only all-female snake species. This gem glitters in his first of Bishop Museum series of papers (1974). Binary characters—required for cladistic analysis—were, in his view, intellectually dishonest. Boy, did we fight about this. He never generated a character matrix leaving it for others to mine his work for veins of anatomy gold. For any serious student of squamate anatomy, the best advice possible would be: "read and understand the work of Sam McDowell."

I met Sam during my first visit to the AMNH in the summer of 1977. Sam and Rosa let me stay with them during my time in New York. Sam did not attend meetings very often and spent most of his life in New York City. Thus, many people never got an impression of Sam's physical stature. When we met he would have been about 50 years old—tall, at least my height (6'3"), robust, already grey-bearded and grey-headed. I never saw him without a beard. He had large hands and long, slightly re-curved fingers, stained with tobacco and preservatives from pickled snakes (he never wore latex gloves during his dissecting). His fingers seemed to arch backwards even more when holding an often-present cigar away from his body. Although not tanned, his complexion was dark and his gaze was direct and intense; he could seem very intimidating. His expression often reflected concentration, but might have been perceived as irritation or even anger. When really listening, he would slightly close his eyes while twisting his beard. His smile was gentle, but coffee and tobacco took an inevitable toll. Sam's laugh was reserved, and punctuated with small deep chuckles that seemed to come from his chest. He almost always wore a jacket, and short-sleeved button-down shirts, often with small holes from old fallen cigar embers. His wardrobe seemed an afterthought, a classic academic anti-fashion statement. His tie might bear a water mark from dipping into some jar or vat of specimens. On the surface, Sam was the picture of an absent-minded professor with a bit of stubborn honesty that disguised a deeply compassionate and passionate humanist.

For someone whose mind was so well organized, his office and research spaces were almost catastrophically disordered. Piles of papers, bottles of specimens, dissecting equipment—all mixed with a light dusting of cigar ash—gave the mistaken impression of neglect. His rotary telephone at the AMNH was a victim, covered in ash except for the dial, which was polished clean by the need to dial numbers.

Sam was not an extravagant person. He lived modestly, enjoyed watching those damn Yankees win, and liked to thrash me in a friendly game of chess. In fact, in days when communication involved writing letters, his notes to me often began with a chess move—P to Q4. His wardrobe changed little over the years. Even his cigars were cheap. In spite of the importance of his scientific contributions, he was never one for self-promotion. After retirement in 1995, Sam lived quietly in his Manhattan, New York neighborhood. He shared four more years with Rosa before she died; they were married for 47 years. Sam lived another 15 years and he was healthy and fit until the last few days of his life. He lost some weight without Rosa and age bent him a bit. He was napping while Janet sat nearby, knitting neglected, when he peacefully and gently died.

Sam only had two graduate students: me and Edward Saiff (Ramapo College of New Jersey). He had mixed feelings about Rutgers-Newark as a grad school and only encouraged me to come because he was able to arrange for me to be a student researcher at the AMNH.

There are very few pictures of Sam. His daughter Janet tells me he disliked having his picture taken. In May 2014, seven

months before he died, a photographer took his picture as a part of the *Humans of New York* project (Fig. 4). The photographer explained to Sam that he had taken thousands of pictures of New Yorkers and he had learned a little something about each person he photographed. Sam responded: "Well, you're not finding out a thing about me!"—as Rosa would say with a little smile and upward glance "Oh, Sam"—true to himself—always.

Acknowledgments.—Reconstructing a life through the concatenation of vignettes is an entirely unsatisfactory process. Thus, I have felt inadequate to the task of characterizing my friend and mentor. I have tried to be honest and understanding. This was helped by the kindness and generosity of those who knew Sam and some who didn't. I am especially grateful for Janet McDowell's help. She provided details, read drafts, and corrected mistakes. Most of all, she liked what I had written, thereby soothing my worries and insecurities. I am also very grateful to Kevin Padian for his deft editorial hand; the result is so much better thanks to his help. Thanks to my long-time friend Douglas Preston. He read a draft and made my head spin with a few words of encouragement. David Cundall and Alan Savitzky usefully provided excellent and thought-provoking evaluations of Sam's scholarly contributions to snake systematics and comparative anatomy. They allowed me to freely crib from their comments. Harry Greene provided generous commentary and the story of a watermarked tie. Jay Cole shared his recollections of Sam's practice of including important findings in larger works. Others who helped include Elizabeth Hotaling and Douglas Morrison, both colleagues of Sam at Rutgers-Newark, as well as other snake researchers including Fran Irish and Olivier Rieppel. And I thank Doris Crumly, who knew Sam almost as long as I did and listened to "Sam" stories—often the same stories years after year.

James Albert Organ (1931–2015)

James (Jim) Albert Organ was considered a great educator by his students and peers. He made significant contributions to the field of plethodontid salamander courtship and ecology, and will be long remembered as an ambassador for plethodontid salamander conservation in the Mount Rogers National Recreation Area in southwestern Virginia. Unbeknown to most, Jim played a pivotal role in the establishment of the Society for the Study of Amphibians and Reptiles.

FIG. 1. Jim Organ at MacDill Air Force Base, Florida, processing snakes he had collected (1950).

Jim Organ was born on 29 March 1931 in Newark, New Jersey. He developed his passion for science while participating in the junior museum program at the Newark Museum; he became a life member at the age of nine. Initially, Jim was more interested in building airplane models, but a field trip to a local swamp stimulated his passion for natural history. At ten years of age, Jim was introduced to salamanders by Frankie Culpepper Georges from Cornell University. From her, Jim gained an understanding of how little was known about this animal group. Many years later Jim thanked Dr. Georges for inspiring him to study salamanders.

In the eighth grade, while attending St. Michael's Catholic School, he wanted to read Charles Darwin's *Origin of Species* for a book report, but the school's nuns deemed the book inappropriate. The Newark Museum staff then recommended to Jim that he attend the engineering program at Central Commercial Technical High School. He graduated in June 1948. Immediately after high school Jim enlisted in the U.S. Air Force. He wanted to be a pilot, but his young age prevented him from entering the program and he was later assigned to supply and logistics. Jim completed training at Mitchel Air Force Base on Long Island, and spent the last years of his military service at Air Force bases in Florida where he was able to continue to pursue herpetology in his down time (Fig. 1). He was honorably discharged in 1952 at the rank of staff sergeant.

After serving in the Air Force, Jim attended the Newark College of Arts and Sciences at Rutgers University where he focused on natural history. He earned an A.B. degree, graduating with high honors in the natural history curriculum and special honors in biology. At Rutgers, Jim meet Della Sprague, a fellow biology major, in an embryology course. Jim and Della were married in 1956, and the couple enjoyed 57 years of marriage until Della's death in 2013 (Fig. 2). Della was almost always with Jim during his field trips and for most of his laboratory courtship trials. Jim credited his accomplishments to a lifetime of help from Della. In 1956, the couple moved to Ann Arbor, Michigan, so Jim could begin graduate school and Della could complete a B.S. in Zoology. They had two daughters Linda Joyce, born in 1960, and Sylvia Fawn, in 1961.

Jim obtained his M.S. (1958) and Ph.D. (1960) degrees from the University of Michigan under the direction of Charles M. Walker. Jim's graduate research was conducted on Whitetop Mount and Mount Rogers in the Jefferson National Forest in southwestern Virginia. Walker initially suggested that Jim work on systematics in Mexico or Guatemala, but Jim had fallen in love with salamanders and southwest Virginia. In 1956, Jim took a field trip to the southern Appalachian Mountains to follow the trail, literally and figuratively, established by Emmitt Reid Dunn. After he and Della were married, they revisited the Southern Appalachians to scout for research locations. They decided that Whitetop Mountain would be his primary research location. He sensed that herpetologists often felt they had to explore other countries because everything had been accomplished in the United States. However, he was the first to acknowledge that there was an immense amount of knowledge lacking for southern Appalachian plethodontid salamanders. He was always delighted when young scientists became dedicated to research Appalachian salamanders. Jim encouraged natural history students of all ages to pursue their passion even in an age where natural history and field work were often considered inferior to molecular work. In an interview with Rick Van Noy for his book *A Nature Sense of Wonder*, Jim said "The best scientists are the ones that never quite grow up. They retain a kind of wonder about them" (Van Noy 2008). This quote is very fitting because Jim always wanted to learn more about herpetology in general and Appalachian salamanders in particular. He read each new issue of the *Journal of Herpetology*, *Herpetological Review*, and *Copeia* until the end of his life.

Jim's master's thesis was on the courtship and reproduction of *Plethodon jordani* (now *montanus*) and *P. glutinosus* (now *cylindraceous*), as well as the life history of *P. welleri* (Organ 1958, 1960a, 1960b). Jim and Della observed courtship of *P. montanus* during their first field trip to Whitetop Mountain in 1956. He wrote a manuscript detailing courtship including drawings of spermatophores. However, Walker would not allow Organ to publish the manuscript because he thought the spermatophore resembled a phallus. During the next season, Jim observed courtship again, but this time he took photographs. Once Walker observed the photographs, he then agreed to allow Jim to publish the manuscript which became Jim's first scientific paper (Organ 1958).

For his dissertation, Jim wanted to expand upon the work of Nelson Hairston (1949) in North Carolina where he had documented elevational gradients of plethodontid salamanders. He established elevational transects at 100 ft intervals on northern

**Corresponding author; e-mail: khamed@vhcc.edu*

and southern slopes of Whitetop and Bluff Mountains, as well as on Mount Rogers. Jim's dissertation work created the foundation for a long term study to examine elevational distributions in what is now called the Mount Rogers National Recreation Area (MRNRA) established by congress in 1966. Additionally, his dissertation research included life histories, population ecology, and reproduction of five species of desmognathine salamanders (Organ 1961a). During his research, he collected over 12,000 specimens, 7,000 of which were *Desmognathus*. All specimens are in the University of Michigan Museum of Zoology where Jim worked during his graduate degree. Jim published his elevational distribution research with *Desmognathus* salamanders in his 1961 *Ecological Monographs* paper (Organ 1961a). It was later included in the 1964 edition of *Readings in Population and Community Ecology* (Hazen 1964).

Jim and Della Organ's lifetime of research on plethodontid salamander courtship and reproduction created a foundation that researchers continue to build upon. In addition to Jim's publication on the courtship of *Plethodon montanus*, he also documented the reproduction and life history of *Gyrinophilus porphyriticus* and *Desmognathus wright* (now *organi*) (Organ 1961b, 1961c). From his work at the University of Virginia's Mountain Lake Biological Station (MLBS) and City College of New York, Jim published three additional papers on salamander behavior and reproduction of *Eurycea lucifuga*, *Plethodon glutinosus*, and *Pseudotriton ruber* (Organ 1968a, 1968b; Organ and Organ 1968).

Jim continued to work within the MRNRA and focused on his long term studies of salamander distributions. He published an abstract from the 1967 SSAR symposium in which he pointed out the absence of long term salamander population studies (Organ 1968c). In 1990 and 1991, the U.S. Forest Service (USFS) contracted with Jim and Della to repeat his dissertation surveys and to survey additional areas within the MRNRA, including Beech Mountain (Fig. 3; Organ 1990, 1991). Based on his research and recommendations, the Forest Service created and then almost doubled the size of its salamander management zone that protects most areas above 4,000 ft within the MRNRA and additional sensitive areas at lower elevations. Jim recommended that commercial collection of salamanders for fishing bait be prohibited long before others had considered the conservation practice. Jim also suggested the MRNRA staff examine collection requests carefully to ensure they had scientific merit. *Desmognathus organi* (formerly *D. wright*; Northern Pygmy Salamander) was named after Jim Organ for lifetime of salamander conservation (Crespi et al. 2010).

For 31 years (1961–1992) Jim was a faculty member at The City College of the City University of New York, his only academic position in his career. During his tenure, Jim served as the department chair for six years, as well as head of the executive office of the Ph.D. program from 1981–1984. Jim had a reputation for being a rigorous professor and was awarded college teacher of the year in 1989. Jim taught a variety of courses, including general biology, zoology, and anatomy. He developed a lab manual for his vertebrate biology course (Organ 1972). Students who completed his course were thankful for his rigor and thoroughness. Later in life, Jim developed health concerns and visited a new doctor in Marion, Virginia. After the visit, the doctor left the examination room and returned a few minutes later with a smile on his face. "I thought you might be that Jim Organ," the doctor stated. One of the doctor's friends in medical school was a graduate of the City College and had successfully completed Jim's anatomy course. After leaving the room, the doctor had quickly called his friend to confirm Jim's identify and said his friend had noted the rigor in Jim's classes.

FIG. 2. Jim and Della Organ at the Mount Rogers Naturalist Rally, Konnarock, Virginia (2003).

FIG. 3. Jim Organ working in his Konnarock, Virginia, cabin during his 1990–1991 resurveys of the MRNRA (note the map of the MRNRA and sampling areas on the wall above the desk).

Kraig Adler and Jim shared lab space at MLBS in 1966 and 1967. Adler had mentioned to Jim that he and others were having trouble naming a new national herpetology society that had been formed in 1958 as the Ohio Herpetological Society. Jim suggested the "Society for the Study of Reptiles and Amphibians." After a brief discussion, Jim and Kraig thought it would be better to follow taxonomic order and the name was modified to the Society for the Study of Amphibians and Reptiles. Kraig presented the potential name for the society at the 1966 meeting in Pittsburgh where it was adopted. Jim co-chaired the SSAR meeting at Mountain Lake Biological Station in 1968.

Later in retirement, Jim and Della continued to share their love and knowledge of southern Appalachian salamanders. They often led interpretive hikes and presented programs on salamanders. Jim was the keynote speaker for the Mount Rogers Naturalist Rally in 1996 and the Tennessee Herpetological Society in 2007. Jim guided many researchers working in the MRNRA and provided advice and insight for modern resurveys of his

historical datasets conducted by Hamed. Jim and Della would open their home to visiting researchers, as well as college and university field trip groups. Everyone who spent time with the Organs relished their knowledge of plethodontid salamanders, as well as their stories of a lifetime of field work. Jim and Della were also great salamander ambassadors to the local community surrounding the MRNRA. Fears of endangered species and land seizures were often calmed with Jim's knowledgeable discussions and personal conversations. Based on his research, Jim felt a few areas within the MRNRA lacked woody cover objects. While eating at a local restaurant, Jim was approached by a Konnarock, Virginia, resident who stated "you want to cut down trees for salamanders?" Jim promptly began a discussion about his recommendation and the need for cover objects. Local residents knew Jim and Della and they were well respected. Some local residents coined the nickname the "salamaster", which was fitting.

Jim Organ died on 16 January 2015 in Konnarock, Virginia, in the cabin he and Della built and where they spent summers until his retirement when it then became their permanent residence. Jim was surrounded by family and friends during his last few months. His impact on his students and the field of plethodontid salamander behavior and ecology, especially in the MRNRA, will be long remembered and serve as a testament to a lifetime of hard work dedicated to a salamander-rich area.

Portions of this obituary were derived from Walls et al. (2014).

CURRENT RESEARCH

The purpose of Current Research is to present brief summaries and citations for selected papers from journals other than those published by the American Society of Ichthyologists and Herpetologists, The Herpetologists' League, and the Society for the Study of Amphibians and Reptiles. Limited space prohibits comprehensive coverage of the literature, but an effort will be made to cover a variety of taxa and topics. To ensure that the coverage is as broad and current as possible, authors are invited to send reprints to the Current Research section editors, Ben Lowe or Chava Weitzman; e-mail addresses may be found on the inside front cover.

Freezing as a Method for Euthanasia

Over the last few decades, methods for euthanizing small reptiles and amphibians have been under scrutiny. One method widely used historically, though currently out of favor, is a combination of cooling and freezing. Concerns about ice crystals forming while the animals are still conscious and therefore exposed to severe pain have led to a perception that this method is not sufficiently humane. The authors of this study investigated the effects of freezing on Cane Toads (*Rhinella marina*) in Australia, where an efficient method for disposing of large quantities of toads is needed and where the freezing method is frequently employed. The authors initially implanted electroencephalogram electrodes to anesthetized toads. Ten days after recovery from surgery, the toads were implanted with a thermocouple wire to monitor body temperature, and then subjected to cooling and freezing. Toads were initially cooled to 5°C in a refrigerator, after which they were placed in a freezer. These experiments revealed a linear decline in braid activity with declining temperature, and no evidence of brain activity spikes consistent with pain associated with freezing. The authors also investigated pertinent literature, demonstrating that research contradicts anti-freezing arguments. Specifically, the brain temperature reflects air temperature, body tissues freeze at temperatures below 0°C, cold is a general anesthetic, and, at least in Cane Toads, brain function effectively ceases at 3.2°C. The authors argue that experiments and literature support freezing (when combined with cooling) to be a humane method of euthanasia comparable with other widely used methods. However, they caution that these findings may not reflect the effects of freezing euthanasia in larger or cold-adapted species.

Shine, R., J. Amiel, A. J. Munn, M. Stewart, A. L. Vyssotski, and J. A. Lesku. 2015. Is "cooling then freezing" a humane way to kill amphibians and reptiles? Biology Open (*in press*) doi: 10.1242/bio.012179.

Middle Triassic Stem Turtle Provides Insights into Turtle Evolution

In 2008, the discovery of a Late Triassic stem turtle, *Odontochelys*, provided important insights into the evolution of turtles. At 220 million years old, *Odontochelys* represented a transitional stage in turtle evolution. In lieu of a carapace, *Odontochelys* had wide, flat ribs lacking intervening bone, though small neural plates were present adjacent to the vertebrae. Additionally, *Odontochelys* had teeth on the maxilla, premaxilla, dentary, and palatal bones. Like modern turtles, *Odontochelys* possessed a fully developed plastron and its skull lacked temporal fenestrae. The authors of the paper described here announce the discovery of an even older stem turtle. Named *Pappochelys*, it was retrieved from 240 million year old sediments in Germany. Like *Odontochelys*, *Pappochelys* bears teeth on the maxilla, premaxilla, and dentary (dental condition of palatal bones is uncertain). It also possesses expanded ribs but lacks the small neural plates of *Odontochelys*. In place of a plastron, *Pappochelys* possesses a series of enlarged, paired gastralia, forming a jagged lateral margin akin to the margin seen in the plastron of later turtles. Perhaps most exciting is the presence of temporal fenestrae, the diagnostic feature of Diapsida; this is in line with recent molecular analyses recovering turtles as a clade nested within Diapsida. In light of this finding, turtle stem lineages had paired temporal fenestrae which were lost in the lineage leading to *Odontochelys* and extant turtles. The sediments and associated fossils (fish, temnospondyl amphibians, terrestrial diapsids) indicate *Pappochelys* occurred at a lacustrine-terrestrial interface, suggesting either an aquatic or amphibious lifestyle. This discovery lends further support to existing hypotheses regarding the phylogenetic placement of turtles, as well as turtle skull and plastron evolution.

Arboreal Snakes have Disproportionately Long Tails

Previous work has demonstrated a correlation between certain anatomical characteristics and arboreality in snakes, with the theory that they reduce the gravitational effects on the cardiovascular system experienced during vertical climbing. Such potential adaptations include small body width to length ratios, anteriorly positioned hearts, and tissues within the tail resistant to edema. The latter has cascading effects on climbing snakes, as edema reduces blood pressure, thus robbing the brain of vital blood flow. In an effort to determine whether long tails relative to body length can be added to this list, the authors of this paper collected data on 226 species spanning the snake phylogeny. Data was taken from female snakes to standardize the comparisons and to avoid issues associated with the presence of hemipenes. Total, tail, and body length measurements were made, and from these, a relative tail length (RTL) was calculated. Species were assigned to one of three "gravitational habitat" categories: obligatorily arboreal, facultatively arboreal and terrestrial, and non-arboreal (terrestrial and/or aquatic) (saxicolous species were not represented). ANCOVA and ANOVA methods were employed to identify if RTL and total body length varied significantly among the treatments, respectively. As phylogenetic relatedness could itself lead to a correlation between ecology and morphology, a phylogenetic independent contrast (PIC) analysis was conducted. For this, the authors constructed a "supertree" for the included taxa by pulling together phylogenetic information from several previous studies; as the information was derived from different analyses, the branch lengths were set to equal. In this analysis, the discrete gravitational habitat categories were treated as continuous data, with obligatorily arboreal, facultatively arboreal and terrestrial, and non-arboreal forming a continuum from high to low gravitational stress, respectively. These analyses revealed the three categories did indeed differ in RTL; post-hoc analysis found RTL declined with declining arboreality. Meanwhile, non-arboreal snakes were shorter than obligatorily and facultatively arboreal snakes (the latter two categories did not differ in total length). The PIC analysis demonstrated that when phylogenetic relatedness is accounted for, RTL is still positively correlated with increasing arboreality. The authors argue that by increasing RTL, arboreal snakes increase the proportion of the body possessing edema-resistant tissues, thereby counteracting the effects of gravity-induced cardiovascular stress. Further, they point out that total length appears to be constrained in obligatorily arboreal snakes (given selection for longer tails), and that in addition to gravitational stress, selection for maximal gap- spanning ability may be contributing to this, as gap-spanning ability relative to body length decreases with increasing body length.

New Insights into the Evolution of Temperature-Dependent Sex Determination

The potential consequences of climate change for species with temperature-dependent sex determination (TSD) are of pronounced concern to conservation biologists. These concerns

extend to species with otherwise genotypic sex determination (GSD) that exhibit a "temperature override," where certain temperatures cause embryos to undergo sex reversal relative to their genotypic sex. Through analysis of wild populations and experiments in the lab, the authors of this paper aimed to determine the potential effects of climate change for a known temperature override species: Australia's Central Bearded Dragon (*Pogona vitticeps*). In this ZZ/ZW species (where females are the heterogametic sex), high temperatures cause genetic males to develop as females. Blood samples were collected from wild dragons across a swath of their distribution from the northern corner of Victoria to the southwest corner of Queensland. Phenotypic sex was determined through visual inspection and physical manipulation, and genotypic sex was determined via PCR. The PCR procedure involved amplifying a gene on the W chromosome and an autosomal gene (control); in the ensuing gel electrophoresis, PCR product from genetic females would have two bands while those from sex-reversed females would have one. These studies revealed a region with a high proportion of sex-reversed females straddling the border between New South Wales and Queensland. Despite numerous laboratory-based demonstrations of sex reversal in amniote species, this study represents the first documentation of this phenomenon in a wild population. Back in the lab, the authors of this paper subjected clutches of eggs from genetic and sex-reversed females to a suite of temperatures, and raised the resulting offspring to determine genotypic and phenotypic sex. Analysis of the offspring data from the genotypic females indicated the temperature above which sex reversal begins to skew the sex ratio is about 33°C, corroborating previous studies. The sex ratios of the offspring of sex-reversed females followed a common pattern seen in species with TSD: males only at low temperatures and females only at high temperatures. The sex-reversal mechanism in sex-reversed female offspring was more sensitive, with the pivotal temperature being a full degree below that of genetic female offspring. Most surprisingly, eggs from sex-reversed females exhibited a higher frequency of successful hatching. While previous attempts to explain the existence of TSD have focused on adaptive processes, these experiments suggest a novel pathway to TSD, where rising temperatures alone can eliminate genetic females from a temperature-override population in a single generation. Further, if sex-reversed females possess greater fitness than their genetically female counterparts, this may also serve to eliminate GSD from a population.

Environmental Conditions of Yellow-Spotted Monitor Nests

Female Yellow-Spotted Monitors (*Varanus panoptes*) are known to excavate nests in close proximity to one another, forming communal "warrens." These nests serve no additional purpose (e.g., adult estivation) as they are filled with loose soil subsequent to ovipositing. A study researching the nesting behavior of this species was published in 2014 that revealed the nesting burrows of *V. panoptes* to be corkscrew-shaped and up to 3.6 m in depth—the deepest cavities dug strictly for nesting ever recorded for a living vertebrate. The paper described here (from the same research group as the aforementioned 2014 paper) aims to shed light on the function of these deep, spiraled burrows. Noting that they bear a striking resemblance to fossil burrows of a Permian therapsid (*Diictodon*) and a Miocene beaver (*Palaeocastor*), they propose that studying deep helical burrows in an extant species may provide insights into these fossil "*Daimonelix*" (or "devil's corkscrews"). The team found and excavated 52 nests, fifteen of which had viable eggs and the remainder of which were presumably from previous years. In an effort to test the hypothesis that deep, helical burrows served to optimize thermal and/or moisture conditions experienced by eggs, the authors placed data loggers along the length of the rebuilt egg-containing burrows to collect temperature data, and took soil samples for moisture quantification. These temperature data were analyzed using linear mixed-effects models with depth and season as fixed effects and specific burrow as a random effect. Non-linear regression was employed to identify a correlation between moisture and depth. These experiments revealed variation in temperature decreased with increased depth. Relative to deeper depths, shallower depths were not only warmer in the warm season, but also colder in the cold season. Interestingly, despite being of variable depth, there was no significant correlation between nest depth and temperature, suggesting nests are constructed to achieve optimal temperatures. A significant positive correlation between moisture and depth was found. The moisture-content increase from one to three meters was small in an absolute sense but relatively large (37%) as these desert soils are exceptionally dry. The authors discuss in depth other hypotheses attempting to explain helical burrows in *V. panoptes* and other taxa; however, their experiments do support the hypotheses that these burrows serve to optimize temperature and maximize moisture experienced by developing eggs.

Doody, J. S., H. James, K. Colyvas, C. R. McHenry, and S. Clulow. 2015. Deep nesting in a lizard, *déjà vu* devil's corkscrews: first helical reptile burrow and deepest vertebrate nest. Biological Journal of the Linnean Society (*in press*) doi:10.1111/bij.12589.

Underpinnings of Reduced Fertilization Success in Explosive Breeding Males

Although female reproductive output limitation due to gamete depletion is well documented in explosive-breeding anuran species, the degree to which males of these species exhibit this is less understood. The authors of this paper set out to study this phenomenon in Wood Frogs (Ranidae: *Lithobates sylvaticus*). Wood Frogs are among the earliest breeders throughout their range (northern, eastern North America), and while at the breeding sites males do not eat and instead subsist solely on energy stores remaining from the previous fall. With such limited

energy available, it would seem these males would have a limited supply of sperm during a given season. Previous studies of explosively breeding anurans have demonstrated both decreased sperm count and decreased fertilization success with successive matings; however, whether a reduction in sperm count or energy is to blame for this reduced success is unknown. To test this, the authors allowed male frogs to successively mate with three to four gravid females over the course of a few days during two breeding seasons. Prior and subsequent to mating, females were weighed to determine the mass of the eggs, and males were weighed and measured to determine a body condition index. Subsequent to mating, egg masses were brought into the laboratory and allowed to develop to the initiation of hatching, at which point the number of fertilized eggs was determined. These data were analyzed using linear mixed models, with number of fertilized eggs as the dependent variable and mating order, year, mass of eggs, and male body condition as fixed effects. A logistic regression was also run to determine if male condition was correlated with fertilization failure. The authors hypothesized that reduced reproductive success due to diminishing sperm count would result in a gradual decline of fertilization success (as sperm count tapers off gradually), while that due to energy-store depletion would result in complete failure to fertilize following reproductive bouts of normal success. The only significant effect detected was the order of the mating; however, this disappeared when complete fertilization failures were removed, indicating a pattern expected if energy-store depletion is affecting fertilization. Additionally, males that failed to fertilize did not differ in size or body condition from those that successfully fertilized consistently. Taken together, these findings illustrate that despite reduction in sperm count with successive matings, other factors may still underlie the reduced fertilization success seen in explosive breeders.

Swierk, L., J. B. Tennessen, and T. Langkilde. 2015. Sperm depletion may not limit male reproduction in a capital breeder. Biological Journal of the Linnean Society (*in press*) doi:10.1111/bij.12603.

Testing Predatory-Bite Protection Hypothesis for Lizard Armor

Though body armor is commonly assumed to serve to protect soft bodies from crushing predatory bites, this hypothesis is infrequently evaluated in a rigorous fashion. As degree of armament is generally conserved within clades, few 'natural experiments' exist allowing for the testing of these hypotheses. The authors of this paper chose to test hypotheses of armor function in one clade that does show considerable armor diversity: lizards of the family Cordylidae. Lizards in this family possess both dermal bone and keratinized epidermal armor which have been hypothesized as a defense against predatory bites. They chose to investigate five species, including single populations of *Karusasaurus polyzonus*, *Namazonurus peersi*, *Cordylus macropholis*, and *C. cordylus*, and three populations of the Armadillo Lizard (*Ouroborus cataphractus*), which are known to vary in degree of armament. Frozen/thawed but otherwise unpreserved skins were subjected to simulated bites from skulls of four sympatric species of herpestid mongooses that are likely predators of these lizards. This involved attaching a mammal cranium to a force transducer, and determining the force required for each skull to pierce each skin. The authors also used light microscopy to quantify the degree of dermal bone and keratinized epidermis in each skin, indicated by thickness of osteoderm and -keratin thickness, respectively. Using an established protocol, estimates of potential bite force were generated for the skulls based on morphometrics. Two ANOVAs were performed; one using the bite force/skin strength data to identify significant differences in skin strength and bite force, and any interactions between the two, and another to determine if there is variation in armor among the lizard species/populations. Finally, a Spearman rank correlation analysis was performed to determine whether skin toughness and degree of armor are significantly correlated. These analyses demonstrated significant variation among bite forces and skin strengths. Post-hoc tests revealed the skins to be of similar toughness with the exception of the *O. cataphractus* populations, which had significantly tougher skin. Further, significant differences in skin toughness were detected among the *O. cataphractus* populations. Similarly, bite force varied among herpestid species. Taken together, all mongoose species have sufficient bite force to puncture the skin of *K. polyzonus*, *N. peersi*, *C. macropholis*, and *C. cordylus*; as for *O. cataphractus*, one or two populations have skin of sufficient strength to withstand the bite of the three weakest mongooses, though the strongest (*Herpestes ichneumon*, the Egyptian Mongoose) is capable of puncturing the skin of all cordylid species examined. Little difference was detected in the degree of keratinized epidermis, while degree of dermal bone showed more variation and mirrored the observed variation in skin toughness. These experiments demonstrate that dermal bone is the primary contributor to skin strength, though even the toughest skin is susceptible to at least one local predator, implying there may be other factors driving the evolution of armament, including (the authors suggest) aiding in thermoregulation, prohibiting extraction from rocky retreats, and serving as mineral reservoirs.

Researchers Reveal Insights into Social Dynamics of Cottonmouths

Recent studies have greatly expanded our understanding of viperid social behavior, for instance revealing that Timber Rattlesnake (*Crotalus horridus*) individuals can recognize kin and preferentially associate with them. The authors of this paper chose to explore how postnatal maternal attendance affects these behaviors in the Cottonmouth (*Agkistrodon piscivorous*). Gravid females were collected from the wild and allowed to give birth in captivity. Upon birth, clutches were assigned to one of two

treatments: they were either allowed to remain with their mother and their siblings until their first shed (maternal attendance, or MA, treatment) or were removed and placed into solitary confinement (separated, or SE, treatment). In the former treatment, subsequent to shedding, the offspring were also placed in solitary confinement. After six months, snakes were assigned to same-sex pairs so that half were paired with a littermate and half were paired with an unrelated snake. To ensure all paired snakes were either full sibs or unrelated, snakes were paired from different localities, and multiple-paternity clutches were identified via genetic testing. Pairs were recorded interacting and average distance and time entwined was calculated; these data were analyzed using general linear modeling and post-hoc tests. This experiment revealed female kin in the MA treatment showed a high affinity to one another while those in the SE treatment avoided each other. Male kin showed the exact opposite pattern, while the non-kin treatments showed no pattern. These same patterns were also reflected in the time spent entwined. Subsequent to these experiments, the same juveniles were subjected to similar trials with either their mother or an unrelated mother. Analyzed using linear mixed models, these experiments revealed regardless of sex, related juveniles and mothers in the MA treatment showed a higher affinity than their unrelated counterparts. In contrast, pairs in the SE treatment showed highly variable degrees of affinity. Further, the only group that showed a greatly reduced propensity to entwine included mothers and unrelated females, regardless of treatment; thus, contrary to what was seen for siblings, maternal attendance appears much less important for mother-offspring relationships. The authors stress that this and similar studies show that "cryptic sociality" is more widespread than generally recognized, and more investigation into the dynamic of facultative parental care is warranted.

Brazilian Frogs Found to be Venomous

Venom, toxin aligned with a delivery system, is common among snakes but has evolved infrequently across the vertebrate tree. And though the presence of poison glands is a synapomorphy of Amphibia, few amphibians exhibit an associated delivery mechanism. Two closely-related hylid frogs in Brazil, *Aparasphenodon brunoi* from the Atlantic Forest ecoregion and *Corythomantis greeningi* from the Caatinga ecoregion, do fall in the venomous category, as they have potent secretions and affiliated cranial spines which pierce through glands to deliver venom to potential predators. The authors of this study set out to further characterize the venom systems of these frogs. Their experiments revealed secretions from *A. brunoi* had LD50 values of ~4 µg while those from *C. greeningi* were ~50 µg. Compare those scores to those of sympatric pitvipers (*Bolthrops*), who average ~100 µg. Further, experiments wherein mice were injected in the paw with one of several toxin dosages and monitored for changes in volume via a plethysmometer showed that maximum edema from *A. brunoi* and *C. greeningi* occurred in 30 and 60 minutes, respectively, and edema persisted for at least 70 hours. SDS-PAGE experiments demonstrated that venom glands of both species possess diverse protein profiles. Experiments aimed at identifying specific enzyme categories found little evidence for proteases in either species' head glands, but hyaluronidase activity was seen in both; these enzymes are well known in squamate venom for their toxin-dispersing properties, but hitherto unknown in amphibians. Scrutiny of photographs and SEM images established both species possess extensive spines on their skulls serving to deliver toxins, with those of *C. greeningi* being the more dramatic of the two. These spines are particularly conspicuous in the rostral region. Histological sections showed that the head glands of *C. greeningi* are exceptionally large; despite having weaker venom than *A. brunoi*, larger glands and more substantial spines make *C. greeningi* similarly formidable. The authors discuss how when captured, these frogs aggressively flex their head, jabbing their venom-fortified spines into the collector's hand. They argue that other frogs with cranial ornamentation (including several rhacophorid species) should be investigated for similar venom apparatus.

INFORMATION FOR CONTRIBUTORS

Herpetological Review is a peer-reviewed quarterly that publishes, in English, articles and notes concerning the study of amphibians and reptiles, as well as book reviews, commentaries, regional and international herpetological society news, and letters from readers directed to the field of herpetology. Articles reporting the results of experimental research, descriptions of new taxa, or taxonomic revisions are not published in ***HR***, but should be submitted to the ***Journal of Herpetology*** (for information, please refer to: http://www.ssarherps.org/pages/JHinstr.php). To submit a manuscript to ***HR***, please consult the SSAR webpage at:

http://ssarherps.org/publications/journals/herpetological-review/

REPRINTS AND PAGE PROOFS

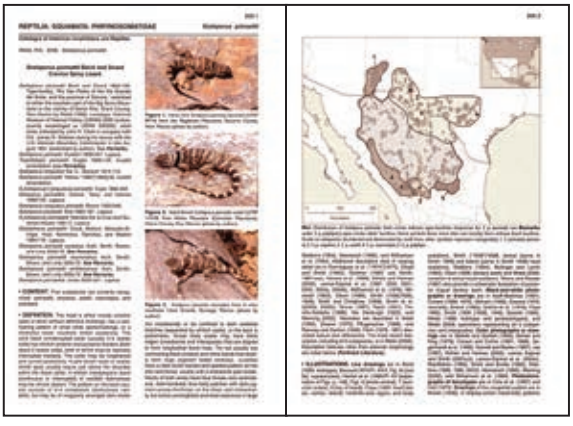
Page proofs are sent electronically to authors of all articles, book reviews, and obituaries, but are not prepared for natural history, geographic distribution, or herpetoculture notes. Proofs are sent as pdf files approximately 2–4 weeks prior to publication. High resolution electronic (pdf) reprints of notes, articles, book reviews, and obituaries are provided at no charge to the primary/corresponding author as a benefit of SSAR membership. Reprint files will normally be sent prior to the issue mailing date from the printer. Authors who are not current SSAR members may purchase pdf reprints from the SSAR Publications Office.

ADVERTISING

Herpetological Review accepts commercial advertising. Rates and copy information are available from the SSAR web page (http://www.ssarherps.org/pages/HRinfo.php).

Herpetological Review (ISSN: 0018-084X) is published quarterly (March, June, September, and December) by the Society for the Study of Amphibians and Reptiles at the Department of Natural Sciences, Williams Baptist College, P.O. Box 3692, Walnut Ridge, AR 72476, USA. Periodicals postage paid at Walnut Ridge, AR 72476 and at additional mailing offices.

All rights reserved. No part of this periodical may be reproduced without written permission of the Editor, except that authors and their agents are permitted to reproduce and distribute their own articles and notes.



POSTMASTER: Send address changes to Breck Bartholomew, SSAR Publications Secretary, P.O. Box 58517, Salt Lake City, UT 84158. **MISSING OR DAMAGED ISSUE?** Please notify Breck Bartholomew, SSAR Publications Secretary (e-mail: ssar@herplit.com) for a replacement.

SSAR PUBLICATIONS

SSAR publishes seven different series: *Journal of Herpetology, Herpetological Review, Facsimile Reprints in Herpetology, Contributions to Herpetology, Herpetological Circulars, Herpetological Conservation*, and the *Catalogue of American Amphibians and Reptiles* (see below for CAAR details). SSAR members receive pre-publication discounts on all *Facsimiles* and *Circulars* and on volumes in the *Contributions* and *Herpetological Conservation* series. A complete pricelist of Society publications is available at: http://www.ssarbooks.com/.

CATALOGUE OF AMERICAN AMPHIBIANS AND REPTILES

The *Catalogue* consists of individual accounts of species and genera prepared by specialists, including synonymy, definition, distribution map, and comprehensive list of literature for each taxon. The accounts cover amphibians and reptiles of the entire Western Hemisphere. As of 2014, SSAR is making all CAAR accounts OPEN ACCESS as a service to the herpetological community. To access individual accounts, visit http://www.ssarcaar.com.

SOCIETY FOR THE STUDY OF AMPHIBIANS AND REPTILES

www.ssarherps.org

The Society for the Study of Amphibians and Reptiles, the largest international herpetological society, is a not-for-profit organization established to advance research, conservation, and education concerning amphibians and reptiles. Founded in 1958, SSAR is widely recognized today as having the most diverse society-sponsored program of services and publications for herpetologists. Membership is open to anyone with an interest in herpetology—professionals and serious amateurs alike—who wish to join with us to advance the goals of the Society.

All members of the SSAR are entitled to vote by mail ballot for Society officers, which allows overseas members to participate in determining the Society's activities; also, many international members attend the annual meetings and serve on editorial boards and committees.

All members and institutions receive the Society's primary technical publication, the *Journal of Herpetology*, and its bulletin, *Herpetological Review*; both are published four times per year. Members also receive pre-publication discounts on other Society publications, which are advertised in *Herpetological Review*.

To join SSAR or to renew your membership, please visit the secure online ZenScientist website via this link:

Discovery of the Critically Endangered Golden Tree Frog, *Phytotriades auratus* (Boulenger, 1917), in Eastern Venezuela, with Comments on its Distribution, Conservation, and Biogeography

The enigmatic hylid *Phytotriades auratus* (Boulenger, 1917), commonly known as the Golden Treefrog, is thought to be an endemic restricted to the two highest peaks in the Northern Range of Trinidad, the main island of the Republic of Trinidad & Tobago:[1] Cerro del Aripo (940 m) and Mount El Tucuche (936 m). In his original description, Boulenger (1917) highlighted the similarity of *P. auratus* with *Amphodus wuchereri*, and described it as *A. auratus*. Bokermann (1966) determined that the genus *Phyllodytes* Wagler, 1830 had priority over *Amphodus* Peters, 1873 and resurrected the former, allocating the two known species (*wuchereri* and *auratus*) to *Phyllodytes*. Since then, nine other species have been added to the genus and all, with the exception of *P. auratus*, are restricted to eastern Brazil (Mata Atlântica). Over 75 years after its initial description, Clarke et al. (1995) provided the first population estimate for *P. auratus*, surveying populations. Their study confirmed the presence of *P. auratus* at El Tucuche and Aripo, ruling out the existence of populations on the other two peaks. Jowers et al. (2008) demonstrated that the genus *Phyllodytes* is paraphyletic on the basis of evidence from mitochondrial genes. They showed that levels of divergence between *P. auratus* and Brazilian *Phyllodytes* were greater than intergeneric distances within the tribe Lophiohylini and erected the genus *Phytotriades* to accommodate the Trinidadian species.

Phytotriades auratus is a bromeliad-dwelling hylid, closely associated with the tank bromeliad *Glomeropitcairnia erectiflora*. Clarke et al. (1995) undertook the first population estimates for the species, surveying Cerro del Aripo (940 m), Mt. Tucuche (936 m), Chaguaramal (859 m), and Morne Bleu (848 m). The study confirmed the presence of Golden Treefrogs on Aripo and El Tucuche. Chaguaramal and Morne Bleu were excluded as possible localities due to the absence of *G. erectiflora*. However, *G. erectiflora* has been mentioned for Chaguaramal, but now this plant seems to have been extirpated from that locality (Clarke et al. 1995).

[1] The term Trinidad & Tobago, with the ampersand, denotes the country. When Trinidad and Tobago is used, connected by the word "and," this refers to the two islands as geological features.

The Discovery of *Phytotriades auratus* in Venezuela

We visited the summit of Cerro Humo, Península de Paria, Sucre State, Venezuela (62.631284°S, 10.692359°W, 1250 m elev.) on 31 August 2014 (ca. 1100 h), to conduct a survey of its conservation status. The summit consists of a very narrow ledge that decreases in width towards the north and is flanked by two steep drop-offs facing east and west, respectively. The widest area of this corridor (ca. 0.5 ha) was cleared in the past to make way for a heliport and communication infrastructure, aimed at finding oil and gas deposits in the Caribbean Basin and the Gulf of Paria, and has subsequently become colonized by herbaceous plants. The southeast face of the ridge is exposed to the trade winds, which allows a high-altitude tropical elfin forest, composed mainly of small trees and epiphytes, to thrive. At present, this elfin forest is confined to the southeastern corner of the summit, extending across no more than 2 ha in size, but having likely occupied most of the area of the summit that was cleared. The main epiphyte bromeliad present within the elfin forest is *Glomeropitcairnia erectiflora*. Below the summit, a moderately disturbed (mostly on the southern face) Tropical Montane Cloud Forest (TMCF) of 208 ha in size surrounds Cerro Humo and its elfin forest.

As we began to document the status of Cerro Humo's summit photographically, the path was blocked by a recently fallen tree trunk with several mature-sized *G. erectiflora* growing on it. Upon closer inspection, we observed movement on one of the *G. erectiflora* and discovered two *P. auratus* moving across the fallen trunk (Fig. 1 A–D). A third specimen was spotted on a nearby *G. erectiflora* growing 40 cm above the ground. Due to the

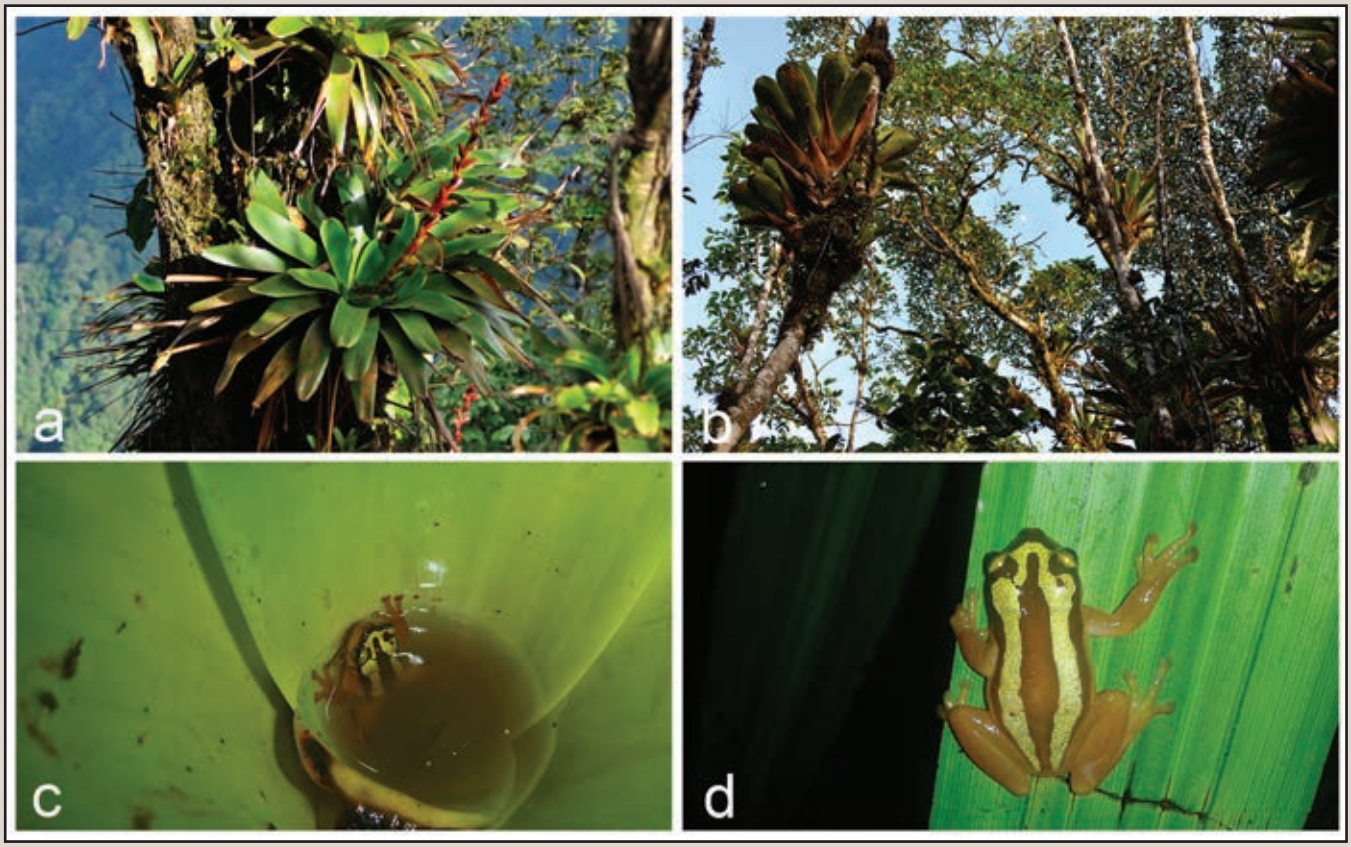

FIG. 1. Communities of *Glomeropitcairnia erectiflora* at the summit of Cerro Humo (A, B). Individual of *Phytotriades auratus* photographed in Cerro Humo and inside the tank of a *G. erectiflora* (C). Dorsal view of same specimen outside the bromeliad (D).

inaccessibility of most bromeliads from the forest floor and our reluctance to begin an invasive survey, no further inspection was carried out; no specimens were collected.

The discovery of this population on Cerro Humo is hardly surprising. Geologically, the Northern Range of Trinidad is considered an extension of the Venezuelan Coastal Cordillera (Beard 1948), and examples of shared flora and fauna between northeastern Venezuela (Turimiquire massif and Península de Paria), and Trinidad and Tobago abound: the gecko *Gonatodes ceciliae* and the marsupial frog *Flectonotus fitzgeraldi* are common both in Península de Paria and on Trinidad. The centrolenid *Hyalinobatrachium orientale* and the White-tailed Sabrewing, *Campylopterus ensipennis,* are both present in Paria, Turimiquire, and on Tobago. Recent herpetofaunal studies in the Península de Paria (e.g., Mijares-Urrutia et al. 2000; Schargel et al. 2005; Rivas et al. 2005; Barrio-Amorós et al. 2006, Manzanilla et al. 1996, 2007; Myers et al. 2009) support the close relationship among northern Trinidad, the Central Coastal Range, the Turimiquire massif, Amazonia, and the Guiana shield. The Península de Paria is catalogued as a "plant refuge" along with the Turimiquire massif, with a large number of representative species also distributed in Trinidad and/or Tobago (Beard 1948; Steyermark 1974, 1979, 1982). It is also an Important Bird Area (IBA VE019, Birdlife) and, along with the Turimiquire massive, is part of a greater Endemic Bird Area (EBA, Birdlife). Lastly, two endangered bird species (*Myioborus pariae* and *Hylonympha macrocerca*) function as trigger species for the Alliance for Zero Extinction (AZE) site VEN8.

Circumstantial evidence might also point to the existence of *P. auratus* on Isla Margarita, Venezuela. In 1964, Janis Roze reported the discovery of three frogs in the axil of a bromeliad on Cerro El Copey (960 m). Although Roze (1964) did not specifically mention the bromeliad species where the frogs were observed, *G. erectiflora* is the most likely candidate, since is the dominant and most abundant bromeliad on the summit of Cerro El Copey, where it even grows at ground level (Hoyos 1985; González 2007). Roze (1964) tentatively assigned the specimens to *Hyla rubra* (= *Scinax ruber*) since Brongersma (1948) had earlier identified a specimen from Guatamare (elev. 50 m) as *S. ruber* but he did so with reservation and called them *Rana del Copey* (the Copey frog); they may represent an undescribed species. More recently, Ugueto and Rivas (2010) reported two specimens of *S. x-signatus* from Juan Griego and Salamanca, respectively (elevations 30 and 50 m). It is very likely that the specimen reported by Brongersma was in fact *S. x-signatus,* and not *S. ruber.* In any case, both *Scinax* species are lowland forms associated with anthropogenic disturbance and floodplains, and it is doubtful that the specimens collected by Roze belonged to either of them. Unfortunately, it is impossible to clarify this, since Roze's specimens were lost. We are inclined to believe that due to the intrinsic synchrony between *G. erectiflora* and *P. auratus,* the *Rana del Copey* might be a *Phytotriades.*

PENÍNSULA DE PARIA, TURIMIQUIRE MASSIF, TRINIDAD AND TOBAGO, A BIOGEOGRAPHICAL CONNECTION

The complex biogeography of Turimiquire/Paria/Trinidad/Tobago is marked by two different events: (A) the "refuge" status with its connection between the flora and fauna of the Amazon, Venezuelan Guayana (Guiana Shield), and the Coastal Range, including its easternmost portion and Trinidad, and (B) the historical detachment of Trinidad and Tobago from

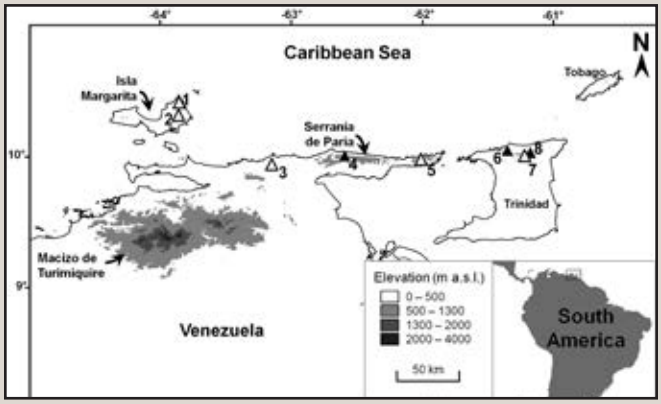

FIG. 2. Map of northeastern Venezuela (including Isla de Margarita), Trinidad, and Tobago showing the known geographic distribution of *Phytotriades auratus* and *Glomeropitcairnia erectiflora.* Black triangles represent localities where *P. auratus* has been recorded from *G. erectiflora* (Kenny 1969; Read 1982; this paper). Open triangles are records of *G. erectiflora* only. Numbers indicate localities as follows: (1) Cerro Tragaplata, (2) Cerro El Copey, (3) Cerro La Cerbatana, (4) Cerro Humo, (5) Cerro Patao, (6) Mount Tucuche, (7) Chaguaramal, (8) Cerro del Aripo. Records of *G. erectiflora* from Venezuela come from Hoyos (1985), Steyermark and Agostini (1966), and Grande and Meier (2012).

the mainland, with later cyclic connections and isolations. Several hypotheses have been put forward to explain the first event: 1) expansion and contraction of tropical forest during humid and dry interglacial and glacial periods respectively, isolating populations of remnant forests, called Quaternary paleoecological refuges; 2) sea transgressions and the formation of the Amazon lagoon during interglacial epochs that could have isolated ancestral populations in elevated areas such as the Atlantic Forest, the Andes, and the Guiana Shield. In both cases, genetic differentiation may have been promoted, allowing allopatric speciation to occur (Grau et al. 2005). The islands of Trinidad and Tobago are not part of the Antillean arc. In fact, Trinidad is part of the continental shelf, while Tobago belongs to the Caribbean Plate, which explains why the latter has been moving eastwards while Trinidad has remained in place. Both islands are reputed to have been connected with the mainland during glacial maxima, when sea levels were lower during the Pliocene and Pleistocene, estimated to have been as low as 180 m below present levels. By that time, between 7 and 4 Myr ago, Tobago was located further west, positioned much closer to the Península de Paria and possibly Isla Margarita, and thereby offered a better position to exchange faunal elements through land connections with the peninsula, as opposed to Trinidad (see Jowers et al. 2014). Such hypotheses cannot fully explain the absence of *H. orientale* and *C. ensipennis* from Trinidad, but particular habitat requirements and/or the ability of different organisms to disperse might have played an important role; nor can local extinctions be discarded.

Conservation Challenges for the Species

Clarke et al. (1995) reported no more than 206 ha of suitable habitat for *P. auratus* in Trinidad. In Venezuela, *P. auratus* has been found in the elfin forest that crowns part of the summit of Cerro Humo. The permanent cloud cover at the summit and its steepness make difficult an exact estimation of the total extension of ideal habitat for the species, but based on field observations we concluded the total area is no more than 20,000 m^2. Nevertheless, the other locations where *G. erectiflora* has been reported in Venezuela, namely, Cerro Patao (elevation 1000 m) and La Cerbatana (elevation 1000 m) in the Península de Paria, and Cerro El Copey on Margarita Island, are potential places where *P. auratus* could be found, and must be surveyed before assessing the taxon at regional scale.

The government of Trinidad & Tobago listed the Golden Treefrog as an Environmental Sensitive Species (ESS) through the Environmental Management Act (EMA) of 2013 (Legal Notice No. 32). The movement was highly anticipated due to the public interest in the EMA, and it represented a major development in terms of the conservation of *P. auratus.* One of the isolated populations of *P. auratus* is already protected as it occurs in habitat included in the Northern Range Game Sanctuary, popularly known as El Tucuche Reserve. Even though *G. erectiflora* is not formally protected, the EMA prohibits any collection, destruction, or removal of *G. erectiflora,* or interference with it and other bromeliad(s), which the ESS inhabits and/or depends on for its survival (EMA 2013).

Despite having important legislation in place to protect sensitive ecosystems and species alike, the Government of Trinidad & Tobago confronts significant declines at both levels, with anthropogenic activities among the main causes. Poor enforcement, inadequate resource allocation, and lack of coordination among stakeholders, were recognized as the main culprits for the tepid performance of Trinidad & Tobago in fulfilling the 2010 Biodiversity Targets (Convention on Biological Diversity 2010).

The discovery of *P. auratus* in Venezuela represents an important development for the conservation of this species, adding another apparently viable population to the initial two from Trinidad, although an extended period of isolation could have resulted in both populations becoming distinct and genetic studies must be undertaken in order to confirm this. Part of the Venezuelan population is located within the boundaries of Península de Paria National Park, which facilitates its conservation. However, the boundary of the park covers only the north face of the peak, leaving more than half of the habitat of *G. erectiflora* and *P. auratus* outside of such protection. The park does not have a code of rules and regulations, and enforcement is, in practice, nonexistent.

The status of Venezuela's environmental decision-making process is a source of utmost concern, particularly its practical implications for research and species conservation. The arrangement of scientific permits has become increasingly difficult, even for members of state's institutions (Rodríguez 2014). The official list of endangered species dates from the 1990s (prohibition of hunting and endangered species) covering 52 mammals, 80 birds, 18 reptiles and 6 amphibians, totaling 156 species (República de Venezuela 1996a, b). The existing conservation programs managed by official institutions cover no more than 12 species (Convention on Biological Diversity 2011), or 8% of the fauna officially listed as endangered. By comparison, the latest version of the national red list, compiled by the Venezuelan NGO Provita and published as the Red Book of Venezuelan Fauna (Rodríguez and Rojas-Suárez 2008), listed 65 mammals, 117 birds, 159 reptiles, 187 amphibians, 221 fishes, and 265 invertebrates as threatened, totaling 1014 species.

The IUCN category of Critically Endangered B1ab(iii)+2ab(iii), accorded by the Global Amphibian Assessment (GAA) to *P. auratus* in 2004, seems to be the most appropriate status for the

Venezuelan population. However, an assessment of the Venezuelan localities for *G. erectiflora* (Cerro Copey in Margarita Island, Cerros La Cerbatana, Patao, El Olvido and Azul in Paria) is needed. Cerro Humo is the highest (1250 m) peak of all of the known locations for *P. auratus* and it provides the largest habitat and therefore may host the largest population of Golden Tree frogs, despite a significant amount of past disturbance from the construction of telecommunications infrastructure and conuco (slash and burn) agriculture. There are just two park guards to oversee 37,500 ha, and the only equipment available are a motorbike and a boat. We have encountered conucos at an elevation of 1000 m on the southern slope of Cerro Humo. More worrisome is the fact that several conucos do not belong to local villagers but to people from remote cities, who are increasingly looking for higher and fresher locations for their crops. Therefore, the lack of enforcement and the precarious situation of the Península de Paria National Park, must be taken into consideration when assessing the taxon. It is also important to note that the state-owned oil company PDVSA is developing a gigantic liquefied gas project on the Península de Paria (PDVSA 2009), and some areas of the national park have already been rezoned to allow infrastructure development. A significant portion of the summit of Cerro Patao (1040 m) has been cleared to allow the installation of telecommunications equipment and a provisional heliport. This could be one of the reasons why *G. erectiflora* was reported for Cerro Patao by Steyermark and Agostini (1966) but appears no longer to be present (De Freitas, unpubl. data). In Venezuela, *G. erectiflora* is considered vulnerable (Delascio et al. 2003).

A recent study of the conservation status of Caribbean Island herpetofauna previews the forthcoming challenges for species such as *P. auratus* in the form of climate change (Hailey and Cazabon-Mannette 2011). The distribution of *P. auratus* is already restricted to the summits of three mountains, and movement to higher elevations in response to rising temperatures is not an option. Likewise, climate change could result in increasing competition from lowland species, as these climb up to higher elevations to seek lower temperatures. Chytridiomycosis could also be an imminent problem; recent research has demonstrated the presence of the causative agent *Batrachochytrium dendrobatidis* in the Aripo River at 447 m on Cerro del Aripo. With an average temperature on the summit of Cerro del Aripo of 18°C, this is within the optimal temperature range (17–25°C) for the growth of *B. dendrobatidis* (Alemu et al. 2013). Populations of *P. auratus* might therefore face extinction, even if global temperature increases are limited to 2°C, the target of the Copenhagen Accord and the *United Nations Framework Convention on Climate Change*. The *P. auratus* population on Cerro Humo, located at 1250 m elevation, might be in a position to withstand a global temperature increase of 1°C, but data reporting the changes in climatic conditions in this locality are lacking. Lastly, the development of an *in situ* conservation program based on the conservation of its fragile habitat could be the best option for the conservation of the species in the long term.

Acknowledgments.—We are indebted to Tito R. Barros, Hinrich Kaiser, John C. Murphy, Angel L. Viloria, and an anonymous reviewer for their valuable comments and suggestions to improve a preliminary version of this work. We are also grateful to Jesus and Calixto Astudillo and Philippe J. R. Kok, for participating in fieldwork and providing necessary literature respectively, and to Marcial Quiroga for making the map. Gilson Rivas was supported financially by the Asociación Colombiana de Zoología to present this work on the IV Congreso Colombiano de Zoología and X Congreso Latinoamericano de Herpetología, held in Cartagena, Colombia, from 1–5 December 2014.

Evaluation of Skin Temperature Measurements as Suitable Surrogates of Body Temperature in Lizards under Field Conditions

Temperature is a crucial factor for ectotherm biology and one of the most accurate methods to study body temperature (T_b) in reptiles is the measurement of cloacal temperature using thermocouples. Albeit being long established, this method has practical limitations as it requires capturing and handling the animal. This may falsify temperature records in smaller species if the animal moves between microhabitats during capture and impedes repeated T_b records under natural, undisturbed conditions. Furthermore, it often restricts sample sizes to small numbers per hour (e.g., Hertz and Huey 1981; Hertz 1992; Grbac and Bauwens 2001). Therefore, cloacal T_b measurements are increasingly replaced by non-invasive thermal measurements that allow repeated temperature records of undisturbed animals in their natural (thermal) environment (Tattersall and Cadena 2010). Two of these alternatives are infrared thermometers (IRT) and the attachment of external temperature loggers (ETL), e.g., Thermochron iButtons. Both methods measure skin temperature (T_{sk}) instead of the actual T_b. Although these methods clearly provide several advantages compared to measurements of cloacal T_b, their use necessitates a validation of the accuracy of such indirect T_b measurements. IRTs allow the measurement of T_{sk} from a relatively large distance (up to 1.5 m, depending on the IRT model) without disturbing the animal. This eases the data collection considerably and facilitates larger sample sizes per hour as well as continuous surveys of single individuals. While ETLs still require the capture and handling of the animal for attachment and removal, they can repeatedly record T_{sk} for

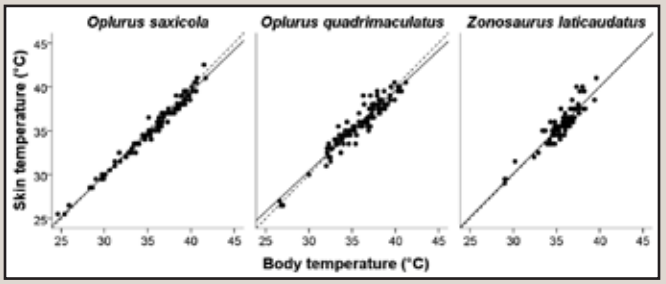

Fig. 1. Comparison of T_{sk} measured with ETLs and T_b measured rectally with a thermocouple. The black line is the regression line (R^2 = 0.979 for *Oplurus saxicola*; R^2 = 0.907 for *O. quadrimaculatus*; R^2 = 0.835 for *Zonosaurus laticaudatus*) and the dotted lined represents a one-to-one line for reference.

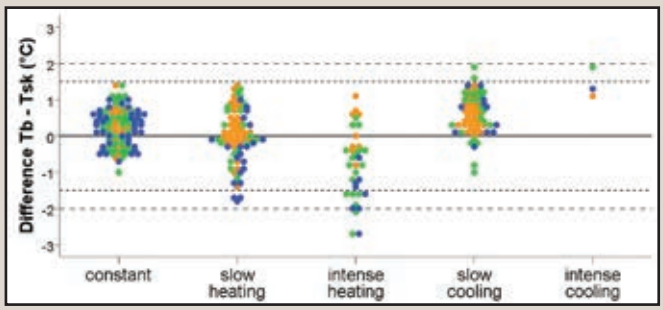

FIG. 2. Discrepancy between T_{sk} measured with ETLs and rectal measurements of T_b according to phases of constant T_b, slow or intense heating and slow or intense cooling of the animal (exemplary also for data from IRTs). The different phases were defined based on the amount of change in T_b during the last five minutes before the measurement of T_{sk}. Constant: $\Delta T_b \leq 0.5$°C, slow heating or cooling: ΔT_b 1.0–4.5°C, intense heating or cooling: $\Delta T_b \geq 5.0$°C. Orange dots show data from *Oplurus saxicola*, green dots from *O. quadrimaculatus*, and blue dots from *Zonosaurus laticaudatus*.

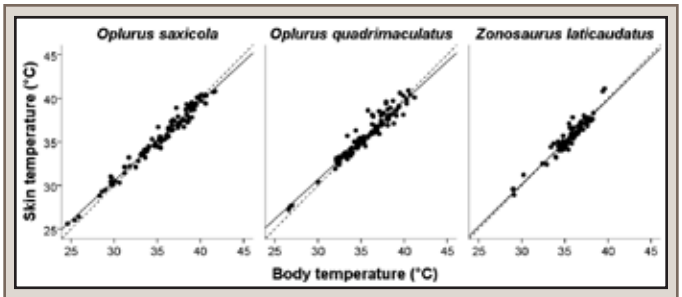

FIG. 3. Comparison of T_{sk} measured with an IRT and T_b measured rectally with a thermocouple. The black line is the regression line (R^2 = 0.974 for *Oplurus saxicola*; R^2 = 0.926 for *O. quadrimaculatus*; R^2 = 0.899 for *Zonosaurus laticaudatus*) and the dotted lined represents a one-to-one line for reference.

several days (and longer) of undisturbed behavior around the clock and even in retreat sites.

Both methods have been applied in previous studies (e.g., Christian et al. 1998; Revell and Hayes 2009; Vasconcelos et al. 2012), but most of the few calibration studies of T_{sk} measurements as surrogates for T_b in reptiles were conducted under laboratory conditions (IRT: Shine et al. 2002; Werner et al. 2005; Herczeg et al. 2006; Hare et al. 2007; Besson and Cree 2010; Carretero 2012; ETL: Shine et al. 2003; Dubois et al. 2008). The laboratory results generally report T_{sk} to be an accurate estimate of T_b, except those reported by Carretero et al. (2012), who report inaccurate results from IRT records in small lacertids (four *Podarcis* spp.) and predict the bias to be even higher for field data. Available field data are scarce and results from Hare et al. (2007) show a significant relationship between T_{sk} and T_b but only with a moderate determination coefficient and sometimes large discrepancies of up to 12.9°C, possibly due to a strong dependence of IRT measurements on the orientation of the device.

The aim of our study was therefore to assess the accuracy of indirect T_b measurements in lizards of different body sizes (20–120 g) under field conditions and to evaluate the suitability of IRT and ETL measurements as an alternative for cloacal temperature records in field studies.

MATERIALS AND METHODS

We chose two iguanid lizards, *Oplurus saxicola* and *O. quadrimaculatus*, and one plated lizard, *Zonosaurus laticaudatus*, all of different body sizes and body mass, to cover a comprehensive range for our calibration study. All three species are endemic to Madagascar and occur sympatrically in rocky habitats. All are diurnal and saxicolous, although *Z. laticaudatus* also searches for its prey in leaf litter and crevices. The study took place in the Andohahela National Park in southeastern Madagascar between November 2009 and April 2012. *Oplurus saxicola*, the smallest of the three species, reaches an average snout–vent length (SVL ± SD) of 8.8 cm ± 0.5 cm and a body mass (BM ± SD) of 21.1 g ± 4.2 g (N = 183). *Oplurus quadrimaculatus* is the largest species of Iguanidae of Madagascar with a SVL of 12.8 cm ± 0.6 cm and a BM of 76.5 g ± 10.5 g (N = 310). The medium-sized gerrhosaurid *Z. laticaudatus* reaches an average SVL of 15.3 cm ± 0.78 cm and a BM of 113.5 g ± 15.9 g (N = 191; W. Berg and O. Theisinger, unpubl.).

Calibration measurements.—We first tested the accuracy of T_{sk} measurements as surrogates for T_b by comparing ETL and IRT records with cloacal T_b measurements in captured *O. saxicola* (101 measurements from six individuals), *O. quadrimaculatus* (102 measurements from eight individuals), and *Z. laticaudatus* (84 measurements from seven individuals). After capturing the animals by noosing, we fixed a temperature logger (iButton model DS1921G; accuracy ± 0.5°C; Maxim Integrated Products Inc., San Jose, California, USA) at the rear end of the animals' backs using a small stripe of duct tape (cut and fitted around the ETL, leaving the top uncovered to avoid insulation). We used unmodified ETLs during this study, weighing 3.3 g each. This corresponds to less than 5% of the body mass for *O. quadrimaculatus* and *Z. laticaudatus* but exceeds the generally recommended 5–10% of the body mass for *O. saxicola* (BM ~20 g). We still attached ETLs to the last species for the duration of the calibration measurements in the box as the additional load did not have any negative effects on the animals' survival or well-being but provided additional information about the comparability of skin and rectal body temperature measurements. The animal was then placed into a transparent plastic box and left in the shade for at least 15 minutes before the start of the calibration. During the test, we moved the box with the animal between sun and shade to create heating and cooling curves. The ETL was programmed to record T_{sk} every minute. At intervals of 5–7 minutes, we took the animal from the box and immediately measured T_{sk} with the IRT (Voltcraft IR 1200 – 50 D; distance to spot ratio 50:1, range from –50°C to +1200°C, resolution 0.1°C, precision ± 1%; Conrad Electronic SE, Hirschau, Germany) from a distance of about 0.5 m to approximate measurements of free ranging animals as closely as possible, which are usually taken from 1–1.5 m distances. Following that, we recorded cloacal T_b using a digital precision thermometer (Greisinger GTH 175/Pt; range from –199.9 to +199.9°C, resolution 0.1°C, precision 0.1°C ± 1 digit; GREISINGER electronic GmbH, Regenstauf, Germany) and returned the animal to the box. Although we avoided hand contact of the ETL and the back of the animal, where IRT records were taken, the animal (and with it the ETL) was exposed to the (differing) ambient temperature for a short time while outside the box. To ensure the comparability of T_{sk} and T_b records, we used the ETL temperature that had been stored immediately before the animal was taken from the box, the IRT record that was measured directly after that and the T_b measurement that was taken within no more than 30 sec after the IRT record.

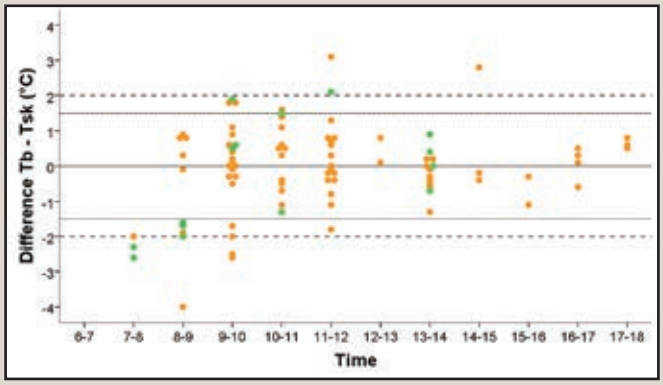

FIG. 4. Discrepancy between T_{sk} measured with an IRT and rectal measurements of T_b in free ranging *Oplurus* according to the time of data collection. Orange dots show data from *O. saxicola*, green dots from *O. quadrimaculatus*.

IRT control measurements of free ranging animals.—To further examine the relationship between T_{sk} and T_b and to ensure the usability of an IRT in the field, we also calibrated this method in free ranging animals of *O. saxicola* (N = 76) and *O. quadrimaculatus* (N = 15). After measuring T_{sk} using the IRT from distances of 1–1.5 m, we also recorded the animals' cloacal T_b if the animals could be captured within no more than 30 s. These control measurements were undertaken at different times of the day and in different microhabitats to maximise the temperature range and compensate for differing environmental conditions.

All devices were calibrated before the measurements and a correction value was subtracted from all IRT temperatures prior to further calculations. Data were processed using IBM SPSS 20 and all means are given with standard deviation.

RESULTS

We recorded a total of 101 paired T_b–T_{sk} calibration measurements from six individuals of *Oplurus saxicola* (7–22 measurements / ind.), 102 paired measurements from eight individuals of *O. quadrimaculatus* (9–22 measurements / ind.), and 84 paired measurements from seven individuals of *Zonosaurus laticaudatus* (4–19 measurements / ind.). During the calibration measurements, T_b ranged from 24.6–41.7°C for *O. saxicola*, 26.6–41.2°C for *O. quadrimaculatus*, and 29.0–39.6°C for *Z. laticaudatus*. This is a comprehensive representation of temperatures found in active individuals of all three species, as our minimum and maximum records of free-ranging individuals show similar activity temperature ranges (28.2–43.6°C for *O. saxicola*, 24.7–41.5°C for *O. quadrimaculatus*, and 28.3–37.4°C for *Z. laticaudatus*).

External temperature loggers.—T_{sk} records from ETLs are highly correlated with T_b (*O. saxicola*: Spearman correlation $r_s = 0.987$, $P < 0.001$, N = 101; *O. quadrimaculatus*: $r_s = 0.933$, $P < 0.001$, N = 102; *Z. laticaudatus*: $r_s = 0.883$, $P < 0.001$, N = 84) and show no differences between paired measurements for *O. quadrimaculatus* (t = 1.315, df = 101, p = 0.191, mean deviation 0.11 ± 0.88°C, max. deviation 2.7°C) and *Z. laticaudatus* (t = –0.637, df = 83, p = 0.526, mean deviation –0.06 ± 0.86°C, max. deviation 2.7°C). However, in *O. saxicola* paired measurements of T_b and T_{sk} differ significantly (t = 6.038, df = 100, p < 0.001, mean deviation 0.33 ± 0.55°C, max. deviation 1.4°C) (Fig. 1). When we assign the paired T_b–T_{sk} measurements to heating and cooling phases of the animals, we can see that the discrepancy is in most cases (98%) smaller than 1.5°C, except for phases of intense heating or cooling, when the ETL heats up or cools down faster than the animal and deviations range up to 2.7°C (Fig. 2).

Infrared thermometer.—T_{sk} readings measured with IRTs are also highly correlated with T_b in all three species (*O. saxicola*: Spearman correlation $r_s = 0.980$, $P < 0.001$, N = 100; *O. quadrimaculatus*: $r_s = 0.943$, $P < 0.001$, N = 102; *Z. laticaudatus*: $r_s = 0.910$, $P < 0.001$, N = 83) and show no differences between paired measurements of T_b and T_{sk} (*O. saxicola*: t = –0.122, df = 99, p = 0.903, mean deviation -0.01 ± 0.66°C, max. deviation 1.7°C; *O. quadrimaculatus*: Wilcoxon test: p = 0.507, mean deviation –0.08 ± 0.78°C, max. deviation 2.8°C; *Z. laticaudatus* Wilcoxon test: p = 0.195, mean deviation 0.04 ± 0.64°C, max. deviation 1.9°C) (Fig. 3).

As in the ETL measurements, deviations of more than 2°C occur only during phases of intense T_b changes and only few measurements (2%) deviate more than 1.5°C during phases when T_b is constant or changes only slowly.

IRT control measurements of free ranging animals.—We took control measurements with the IRT of free ranging *O. saxicola* and *O. quadrimaculatus*. Both species show a high correlation of T_{sk} and T_b also under natural conditions (*O. saxicola*: Spearman correlation $r_s = 0.795$, $P < 0.001$, N = 76; *O. quadrimaculatus*: $r_s = 0.753$, $P < 0.001$, N = 15). Deviations are higher than in the calibration measurements though, with a mean deviation of –0.02 ± 1.14°C and max. deviation of 4.0°C for *O. saxicola* and a mean deviation of –0.29 ± 1.57°C and max. deviation of 2.6°C for *O. quadrimaculatus*. To further analyze these data, we plotted the deviations between T_b and T_{sk} according to the time of data collection (Fig. 4). Of all temperature records of free-ranging *Oplurus* (N = 91), 91% deviate less than 2°C and 78% less than 1.5°C. If records from the early morning (before 0900 h), when animals often heat up 10°C or more within a short period of time, are excluded, 94% of the remaining data (N = 78) deviate less than 2°C and 85% less than 1.5°C.

DISCUSSION

The suitability of ETLs and IRTs as alternatives for cloacal temperature measurements in reptiles largely depends on the applicability of T_{sk} as a substitute for T_b. Our data show a highly significant correlation between T_{sk} and T_b in all three species over a range of body sizes (20–120 g) and neither ETL nor IRT measurements show significant differences between paired T_{sk} and T_b records in *Oplurus quadrimaculatus* and *Zonosaurus laticaudatus*. In *O. saxicola*, ETL measurements of T_{sk} differ significantly from T_b records but T_{sk} measured with an IRT does not. While IRT records show an even distribution of positive and negative deviations, there is a bias in the ETL records of *O. saxicola* towards measurements with $T_{sk} < T_b$ (no bias during heating phases but $T_{sk} < T_b$ during cooling). This is a species-specific problem and due to a loose fit of some of the ETLs during cooling phases, when the animal may switch to thigmothermy and press itself flat against the ground, causing the ETL to partially lose contact with the skin. However, mean deviations are close to 0.0°C in records from both methods and across all three species. Large deviations of more than 2°C occurred only during phases of intense changes in T_b, while phases of slow heating and cooling mostly show deviations < 1.5°C in ETL and IRT measurements (Fig. 2). Our data from free-ranging *Oplurus* confirm this observation and show large deviations with $T_{sk} > T_b$ during morning basking periods, when the animals often heat

up 10°C or more within a short period of time (Theisinger et al., unpubl. data), while large deviations of $T_{sk} < T_b$ were found around midday and in the early afternoon, when the animals retreat from the heat to colder crevices (Fig. 4). Nevertheless, 80% of the records deviated less than 1.5°C and over 90% less than 2°C, confirming ETLs and IRTs as valuable approaches for field measurements of free-ranging animals when potential constraints by rapid changes in T_b, especially in field studies, are considered.

Internal gradients between the surface and the body core are considered to be negligible in models of small reptiles (< 30 g; Bakken 1992). This is generally confirmed by our results from the more standardized calibration tests, during which the skin of *O. quadrimaculatus* (BM ~80 g) and *Z. laticaudatus* (BM ~120 g) heated up faster than the core body during phases of intense heating, while *O. saxicola* (BM ~20 g) shows no clear deviation between T_{sk} and T_b (Fig. 2). However, data from free-ranging individuals show that even animals with a BM of less than 30 g may occasionally experience considerable differences between T_{sk} and T_b when undergoing intense changes in T_b (Fig. 4). Lags between surface and core body temperature during warming phases were also found in small lacertid lizards (BM < 10 g) using an infrared camera (Luna and Font 2013). A thermal inertia between surface and core body in small species thus depends not only on the actual body size but also on the rate of heating.

The use of ETLs is mostly limited by their dimensions. Depending on the model, modifications may be possible that make the device suitable for many smaller species (e.g., in iButtons: a reduction in weight from 3 g to about 1.5 g; Lovegrove 2009) but might affect their functionality. Exceptions are saxicolous species like *O. saxicola*, which live in crevices barely higher than the animals themselves. An external attachment of even just a few millimeters height would restrain these animals from returning to their retreat sites. Furthermore, unmodified ETLs attached to *O. quadrimaculatus* showed such a high degree of abrasion and scratches that a modified logger, usually coated only in wax or silicone instead of a stainless steel capsule, would not last long. To further increase their accuracy, we also tried to color the ETLs according to the animals' backs in order to mimic solar reflection and absorption. We did not find notable differences between painted and unpainted devices and thus continued with unpainted ones, which already show a high and satisfying accuracy. It might, however, be possible to even further increase the accuracy of this method through different types of paint and color. Compared to IRTs, ETLs offer the crucial advantage that they also record the temperature when the animal is out of sight in retreat sites or during times of inactivity and may record the completely undisturbed animal's "thermal behavior" over several days or even weeks, provided that the logger can be recovered.

Technical aspects to consider when using IRTs include animal size in comparison to the IRT metering point. Previous field studies on McCann's Skinks (*Oligosoma maccanni*) found a rather low relationship between T_{sk} and T_b ($r^2 = 0.586$) and great individual differences of up to 12.9°C (Hare et al. 2007) and similar problems were reported for several *Podarcis* forms (Carretero et al. 2012). Despite their effort to ensure that the target laser sights all fell on the posterior abdomen or pelvic region of the animal, Hare et al. (2007) still found a high influence of background temperature on IRT readings and reported better results if the IRT was oriented in line with the skink's body axis. Although we cannot report similar problems from our study (probably due to the larger body size of our study species), this clearly presents a limitation for IRT measurements (and should be considered when choosing a device), especially under field conditions where the difference between background and body temperature is often much greater than in laboratory studies with more consistent temperature regimes. A further consideration when using an IRT in the field is the operating temperature of the device. Depending on the device, the IRT may show abnormal temperatures if it becomes too hot (e.g., through use in direct sunlight). Although our device recovered quickly and continued to show accurate temperatures after cooling down, we recommend protecting the IRT from direct sunlight when using it in environments with extremely high temperatures. If these aspects are considered, IRTs provide a quick and easy way to measure T_{sk} in reptiles and have the advantage that measurements can be taken from larger distances without disturbing the natural behavior of the animals (and those in close proximity). Hence a much larger number of indirect T_b measurements can be recorded per hour in contrast to conventional cloacal T_b records. For example, by implementing IRT measurements during transect walks we took up to 58 indirect T_b records per hour for *O. saxicola*.

In conclusion, our results show a close relationship and high accuracy between T_{sk} and T_b in lizards of different body sizes and thus a high applicability of both methods, ETLs and IRTs. Considerable differences between T_{sk} and T_b occurred only during phases of intense changes in T_b, and were detectable even in lizards with a BM of ~20 g, suggesting that the thermal inertia depends not only on body size but also on the rate of heating. Both methods proved to be easy to use under field conditions if certain limitations are considered. We therefore generally validate the use of T_{sk} measurements as surrogates for cloacal T_b measurements in small to medium sized reptiles (20–120 g) also for field studies, but have to emphasize the importance of restrictions related to the rate of heating, which is not necessarily apparent under standardized lab conditions. The increasing application of IRTs and other external measurements of body temperature in reptiles will expand the potential of field studies by facilitating repeated temperature records of undisturbed animals, larger sample sizes and the collection of data over several days including night times and in retreat sites.

Acknowledgments.—We thank Jörg Ganzhorn for his professional advice and technical support and our anonymous reviewers for their helpful comments on the manuscript. Thanks to our field assistant Maharavo and the staff of the Andohahela National Park. Special thanks to Jacques Rakotondranary and Tolona Andrianasolo for helping us with bureaucratic issues. Our survey was conducted under research permits from Madagascar National Parks (Permission no. 205/11 and 046/12) and all applicable institutional Animal Care guidelines were followed. This work was financially supported by Evangelisches Studienwerk Villigst e.V. and the German Academic Exchange Service (DAAD).

Diet of the Northern Pacific Rattlesnake (*Crotalus o. oreganus*) in California

Data from museum specimens are used to inform a wide range of studies from taxonomy and physiology, to how climate change affects animal distributions (e.g., Moritz et al. 2008; Suarez and Tsutsui 2004; see Pyke and Ehrlich 2010 for review). Analysis of the gut contents of museum specimens is a straightforward and low-cost method of determining the dietary habits of species in the wild, and these data may then be used to help inform conservation programs of at-risk species.

The feeding habits of many species of rattlesnakes have been elucidated with museum studies (for recent examples see Glaudas et al. 2008; Dugan and Hayes 2012). These studies provide initial data that form the backbone for other lines of inquiry such as the relationship between diet and venom composition (Mackessy 1988; Mackessy et al. 2003) and the evolutionary arms race between rattlesnakes and their prey (Biardi et al. 2005; Barlow et al. 2009). We analyzed data on the diet of Northern Pacific Rattlesnakes (*Crotalus o. oreganus*) from California by identifying prey items recovered from dissection of museum specimens. *Crotalus o. oreganus* ranges from central California to northern British Columbia (Stebbins and McGinnis 2012). Several field studies on diet have been conducted near the northern boundary of the range (Macartney 1989; Wallace and Diller 1990), and several were centered closer to the southern edge of the range (Fitch and Twining 1946; Mackessy 1988). Ernst and Ernst (2011) provide an extensive review of the diets of many North American rattlesnakes, including *Crotalus o. oreganus* in various parts of its range. Our museum study included specimens from throughout the California range of this taxon with the goal of filling in a geographical gap. Combined with other published dietary accounts, our study helps contribute to a more robust understanding of the feeding habits of *C. o. oreganus*.

Methods.—Remains of prey were present in the gastrointestinal tracts (stomach and intestines) of 85 specimens of *Crotalus o. oreganus* collected in California and deposited in the Museum of Vertebrate Zoology (MVZ, Berkeley, California) and the Santa Barbara Natural History Museum (SBNHM, Santa Barbara, California). In some cases prey had already been removed from snakes, and in other cases we removed prey items from the stomach and intestines and stored them in ethanol in glass vials. We attempted to avoid snakes from possible intergrade zones with other subspecies (based on range maps). The snout–vent length (SVL) of each snake was measured with a cloth measuring tape. Each snake was categorized as male (N = 45), female (N = 30), or neonate (N = 10). Neonate snakes were identified based on their single rattle segment and uniform small size (range: 245–290 mm SVL).

Prey items were identified to the lowest possible taxon level. In the 85 snakes, 88 prey items (3 snakes had two different prey types present) could be positively identified at least to the level of vertebrate class. These prey items were categorized as amphibians based on presence of identifiable amphibian tissue (e.g., bones),

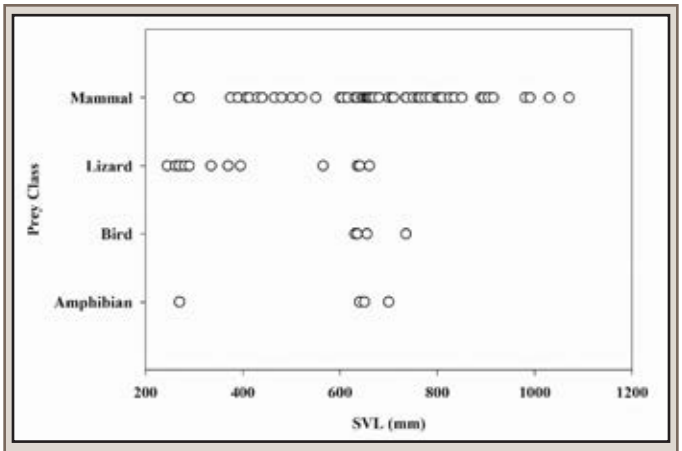

FIG. 1. Prey type distribution based on snout–vent length (SVL) of *Crotalus o. oreganus* in the present study. Each data point represents an individual snake. Snakes that ate lizards were smaller in SVL than snakes that ate mammals and birds; snakes that ate amphibians were not different in size from those that ate other prey types.

as mammals based on presence of hair and/or mammalian teeth, as lizards based on presence of lizard scales, and as birds based on presence of feathers. The majority of prey items were found highly digested in the intestines. However, in cases where prey items were intact or other reliable structures (e.g., teeth) were well preserved (N = 52), we identified prey to taxonomic levels below class (e.g., order, family, genus, or species).

The size of snakes that consumed each prey class was compared by ANOVA on square-root-transformed snake SVL. Post hoc Tukey's tests were used for pairwise comparisons. To test the hypothesis that juvenile snakes consumed lizards more frequently than adults, snakes were assigned to two groups: immature/juvenile (< 520 mm [Diller and Wallace 2002], including neonates) and adult (520 mm or greater). Chi-square likelihood-ratio tests were used to compare the proportion of individuals containing lizard prey within the two groups. The effect of sex on diet composition was also examined using likelihood-ratio tests using adults only. The presence of sexual size dimorphism was tested using a student's t-test on log-transformed data. All analyses were conducted in JMP Pro 11 (SAS Institute Inc.).

Results.—Prey from three vertebrate classes were represented: Amphibia, Reptilia (lizards and birds), and Mammalia (Table 1). We broke down reptilian prey into lizards and birds for the purpose of analysis. Mammal prey were most common (76.1%), followed by lizards (14.8%), birds (4.5%), and amphibians (4.5%). Only 3 snakes contained prey items from more than one prey class; we treated them as independent samples because deleting these data did not affect the results of the analysis. There was a significant difference in the size of individuals that preyed upon the different prey classes ($F_{3,87} = 11.06$, $P < 0.001$; Fig. 1). Post-hoc analyses showed that snakes that consumed lizards were significantly smaller compared to those that ate mammals and birds, which were not different in size from each other or from those that consumed amphibians. Compared to adults, snakes classified as juveniles based on SVL preyed more on lizards ($\chi^2 = 15.0$, $P < 0.001$). Adult males and females did not significantly differ in size ($T = 1.45$, $P = 0.15$), or diet (All classes: $\chi^2 = 2.44$, $P = 0.49$, Proportion lizard: $\chi^2 = 2.15$, $P = 0.14$). The majority of neonates (60%, 6 of 10) examined had consumed lizard prey, followed by small mammals (30%, 3 of 10) and amphibians (10%, 1 of 10).

Of the 88 prey items, we were able to identify the following specific prey taxa (See Table 1 for details): Anuran (species not identified), Arboreal Salamander, *Aneides lugubris*, Gilbert's Skink, *Plestiodon gilberti*, Western Skink, *P. skiltonianus*, Sagebrush Lizard, *Sceloporus graciosus*, Western Fence Lizard, *S. occidentalis*, *Sceloporus* sp., Side-blotched Lizard, *Uta stansburiana*, Warbler, family Paruidae, Rabbit, *Sylvilagus* sp., American Pika, *Ochotona princeps*, Mountain Beaver, *Aplodontia rufa*, California Vole, *Microtus californicus*, *Microtus* sp., Dusky-footed Woodrat, *Neotoma fuscipes*, Southern Grasshopper Mouse, *Onychomys torridus*, *Onychomys* sp., Deer Mouse, *Peromyscus maniculatus*, Western Harvest Mouse, *Reithrodontomys megalotis*, Kangaroo Rat, *Dipodomys* sp., and California Ground Squirrel, *Otospermophilus beecheyi*.

Discussion.—The diet of *C. o. oreganus* has been studied in several field studies (Fitch and Twining 1946; Macartney 1989; Wallace and Diller 1990). Each of these studies examined one or a small group of populations in restricted geographic localities (central California: Fitch and Twining 1946, northern Idaho: Wallace and Diller 1990; British Columbia, Canada: Macartney 1989; Central Washington: Weaver and Lahti 2005). Our goal in the present study was to conduct an investigation of the diet of *C. o. oreganus* in its range throughout California (central California to the Oregon border) using museum specimens, which will help to fill in gaps in our knowledge of types of prey consumed by *C. o. oreganus* in the southern part of its range.

Our study agrees with previous field studies that the majority of the diet of *C. o. oreganus* consists of small rodents. A report on diet in central Washington shows a similar prey class distribution compared to our results for California populations (74% mammal, 20% lizard, and 6% bird; Weaver and Lahti 2005). Studies at the far northern part of the range found that the diet consists almost entirely of mammals, primarily rodents, and a small number of birds and lizards (Macartney 1989; Wallace and Diller 1990). In these studies, neonates ate mainly small mammals such as shrews; in our study, neonates also ate small mammals but ate lizards at a higher frequency than mammals. The higher prevalence of lizard prey found in our California snakes compared to snakes in northern populations could reflect a greater abundance of lizards in California than in northern parts of the range. Mackessy (1988) also found that lizards made up a large portion of the diet of juvenile *C. o. helleri* in central California, and that snakes larger than 500 mm total length ate mammals rather than lizards. In our study, we found that some juvenile *C. o. oreganus* (< 520 mm SVL) ate mammals and some snakes larger than 520 mm ate lizards; nevertheless, the general trend of an ontogenetic shift from a diet primarily of lizards to one primarily of mammals is supported (Fig. 1). Mackessy (1988) also showed that the venom composition of *C. o. helleri* and *C. o. oreganus* changes ontogenetically, with smaller snakes having higher venom toxicity. The ontogenetic shift in venom composition in *C. o. oreganus* may relate to a change in diet from primarily lizards to primarily mammals. Such a shift in diet was first suggested by Fitch and Twining (1946) and is evidenced in our study by the fact that neonates ate many lizards but adults did not. It is therefore possible that neonate *C. o. oreganus* at the southern part of the range have evolved venom more suited towards eating lizards compared to neonates at the northern end of the range, which may encounter lizards more rarely. This hypothesis could be tested by obtaining data on lizard densities as well as the toxicity of neonate venom along a latitudinal cline from central California to southern Canada.

TABLE 1. List of food items consumed by *Crotalus o. oreganus* throughout its range summarized from four studies conducted on populations throughout the range, including this study on California snakes. Prey taxa are listed within vertebrate class, alphabetically by family and then genus and species. Percentages in bold are range-wide percentages for each vertebrate class. Percentages not in bold are those reported in each study. Blank values indicate information was not available.

*Sample size was not reported in the study.
**Raw sample sizes not reported, numbers were back-calculated from reported percentages and rounded to the nearest whole number.

Several unusual prey records have been recorded for *C. o. oreganus*. Bullard and Fox (2002) report an adult male *C. o. oreganus* that had eaten a Rubber Boa (*Charina bottae*). Cannibalism has not been reported in *C. o. oreganus*, but there are several reports of closely related species eating conspecifics (Gloyd 1933; Lillywhite 1982). Our study revealed two new prey genera for *C. o. oreganus*: Mountain Beavers, *Aplodontia rufa*, and Grasshopper Mice, *Onychomys*. Two individuals consumed Mountain Beavers (based on identification of claws in gut contents). That Mountain Beavers have not previously been identified in studies of *C. o. oreganus* diet is likely because few field studies have been conducted at montane sites within the range of this prey taxon. This highlights the importance of museum studies in filling in the gaps in our knowledge of the feeding habits of species over large geographic areas. Taken together, the results of range-wide studies (summarized from four comprehensive studies in Table 1 and reviewed in detail in Ernst and Ernst 2011 and Klauber 1956), reveal that adult *C. o. oreganus* prey upon diverse mammalian taxa throughout their range and that juveniles in the central and southern portions of the range prey more frequently on lizards compared to adults and juveniles from northern populations.

Courtship Behavior of *Bokermannohyla alvarengai*, a Waltzing Anuran

Courtship in anurans may be very unpredictable, which renders it considerably difficult to observe. Consequently, we lack courtship information for the majority of the currently recognized species. That is the case for the genus *Bokermannohyla* Faivovich, Haddad, Garcia, Frost, Campbell and Wheeler 2005, which is composed of 32 species (Frost 2015), for which information on courtship behavior is limited to two species, *B. ibitiguara* (Cardoso 1983) and *B. nanuzae* (Bokermann and Sazima 1973) (Nali and Prado 2012; Lima et al. 2014). *Bokermannohyla* is included in the tribe Cophomantini, with *Aplastodiscus, Hyloscirtus, Hypsiboas,* and *Myersiohyla* (Faivovich et al. 2005). Among these there are no literature records about courtship behavior in *Hyloscirtus* and *Myersiohyla*; there is some information for *Hypsiboas* (Hödl 1977; Kluge 1981; Martins and Haddad 1988; Menin et al 2004; Camurugi and Juncá 2013; Landestoy 2013); and *Aplastodiscus* is better known (Haddad and Sawaya 2000; Hartmann et al. 2004; Haddad et al. 2005; Carvalho Jr. et al. 2006; Zina and Haddad 2007). Herein, we provide information about the courtship behavior of *Bokermannohyla alvarengai* (Bokermann 1956) in attempt to fill the void of information on courtship behavior within this clade.

Bokermannohyla alvarengai (Fig. 1) is a large treefrog (up to 140 mm snout–vent length, SVL; see Lugli and Haddad 2006) inhabiting rocky meadows at elevations above 1000 m in southeastern Brazil. Its natural history is poorly understood, including reproductive biology, with most of the information available based on a few reports (e.g., Sazima and Bokermann 1977; Eterovick and Sazima 2000; Eterovick and Sazima 2004). This frog breeds in temporary, rocky-bottomed streams running on the low and sparse vegetation typical of its habitat at that altitude. As previously reported by Sazima and Bokermann (1977), *B. alvarengai* is a skittish species ceasing all its activities at the slightest disturbance, making it difficult to observe its courtship and mating behavior.

We were able to observe part of the courtship behavior of *B. alvarengai* under natural conditions at Serra do Cipó (19.290783°S, 43.582400°W, SAD69; 1196 m elev.), Minas Gerais state, Brazil. The courtship description is based on one pair of frogs observed during the rainy season on the night of 17 November 2012. The reproductive event lasted about four hours from 2040 h to 0030 h. We used low illumination to minimize disturbance of the frogs. The male was 88.7 mm in SVL and the female, smaller than male, could not be measured as she escaped at the end of the observation. Air temperature was 19.2°C, relative humidity was 75.6%, and wind speed varied from 0.4 to 1 m/sec.

The courtship behavior of *Bokermannohyla alvarengai* differed markedly from the congenerics *B. ibitiguara* and *B. nanuzae*, as well as from the other species of Cophomantini. The most striking difference was observed after the more trivial behaviors, such as acoustic, visual, and tactile interaction, when the couple exhibited a unique and previously unreported sequence of complex waltz-like movements in the water. The stages with the sequential progress of the courtship behavior of *B. alvarengai* are described as follows (Fig. 2).

The male was in a small cavity at a vertical earthen wall (ca. 1 m from the ground) eroded by water on the stream edge, facing the watercourse. He was 1.5 m distant from a small shallow puddle (ca. 0.9 x 1.2 m width) surrounded by stones and vegetation, disconnected from the stream by the decrease of water level. Courtship began at 2040 h with the approach of a female into the male's territory. When first sighted, the female was sitting on a small rock near the ground about 1.2 m in front of the male. Ten minutes later, she turned toward him and leapt in his direction, bounced off the earthen wall, and returned to the ground. After a while, the female moved to the same wall remaining 0.5 m below the male in the diagonal (Fig. 2A). The male started calling 20 min after the beginning of observation at 2100 h, and kept calling with long intervals (ranging from 18 to 80 min) between calls until 2325 h. At 2325 h both were observed inside the puddle facing each other with the digits on both front legs interlaced. The frogs were touching and repeatedly bumping their chests. As we did not keep the lights on all the time (between 2040 h and 2325 h), we lost the information about which gender led the partner to the oviposition site. The couple then moved around the puddle using their hind legs to sustain the body describing circular movements with hands still clasped, like dancing a waltz (Fig. 2B). After 1–2 min, they separated and the female submerged 0.2 m deep and the male hid himself under a clump of grass on the opposite edge of the puddle. The male resumed calling and within a

FIG. 1. *Bokermannohyla alvarengai* from Serra do Cipó, state of Minas Gerais, Brazil.

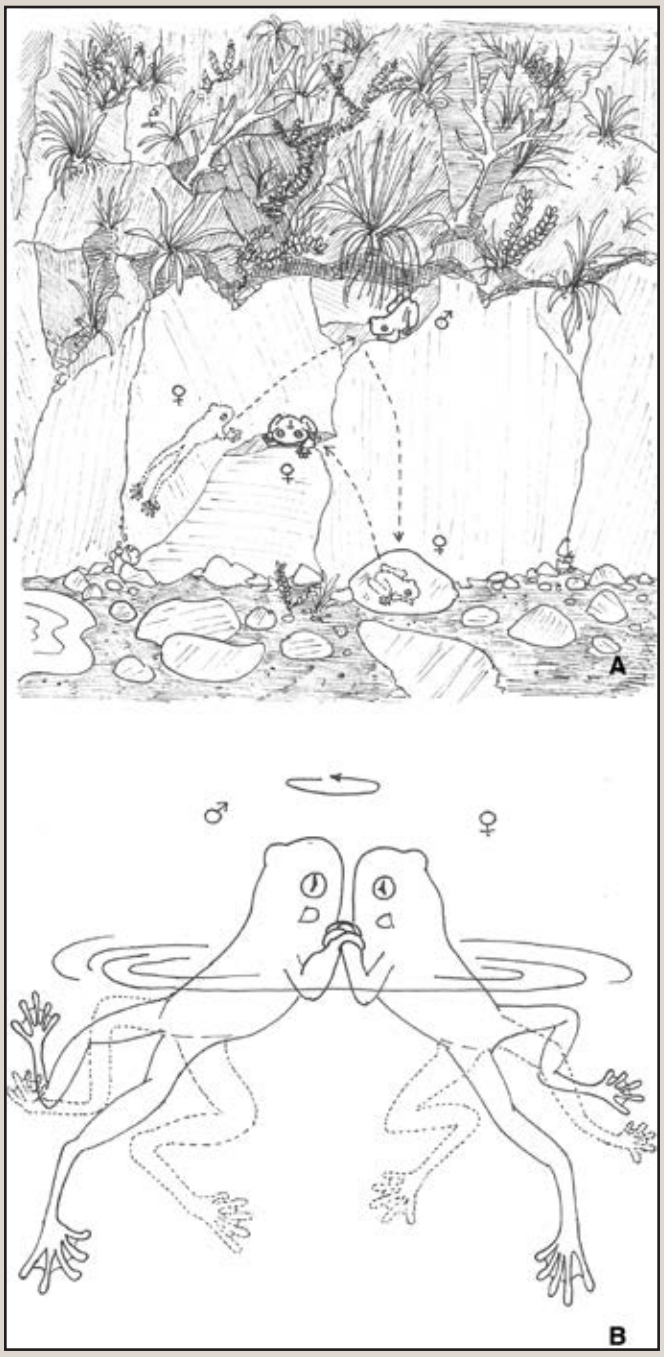

FIG. 2. Courtship in the treefrog *Bokermannohyla alvarengai*. A) female approaches a calling male, leaps to his direction and bounces off the wall, returns to the ground, and moves to the same wall; B) female and male in the puddle with holding hands and toes interlaced in a clasp touching and bumping their chests, and whirling the puddle by treading water using hind legs.

few minutes, the female emerged and followed him to the clump. Both left the grass clump with the front digits again interlaced and moved back to the center of the puddle where they resumed the waltz-like movements circling the puddle for about one minute. Next, the male used his hypertrophied forearms to vigorously try to pull the female underwater while maintaining her in a belly-up position. We interpreted this as an amplexus attempt. At this moment, the female escaped to the puddle edge and slowly moved away by the stream. The male chased her to the edge of the puddle and resumed calling, while watching the female, who apparently ignored his calls and left. The female entered into a crevice of a rock and disappeared while the male continued to call far apart in time. The entire action in the water lasted 20 min after the initial physical contact (at 2325 h).

Despite the fact that the courtship behavior concluded with an unsuccessful attempt of amplexus, we believe that the behavioral sequence observed is a valid description of the pre-mating courtship behavior of *Bokermannohyla alvarengai*. As this species utilizes the reproductive mode number two, laying its eggs in lotic water (Haddad and Prado 2005), it is quite likely that egg deposition would occur in that site. Furthermore, records about clutches in the same study area confirm this kind of oviposition site as preferred by the species (Centeno, pers. obs.).

The courtship of *B. alvarengai* seems to be distinct from other species of Cophomantini. In *B. ibitiguara*, the courtship is more aggressive, with the male hitting the female with his arm to conduct her to the oviposition site (Nali and Prado 2012). In *B. nanuzae*, the female chooses a calling male during courtship behavior, then the male guides the female to the egg-laying site (a natural crevice) using visual, acoustic, and tactile stimuli (Lima et al. 2014). Similarly, in *Aplastodiscus*, the couple exchanges many soft touches with chin, hands, and feet while the male conducts the female to the nest built by him (Haddad and Sawaya 2000; Hartmann et al. 2004; Haddad et al. 2005; Carvalho Jr. et al. 2006; Zina and Haddad 2007). The genus *Hypsiboas* presents a more variable array of courtship behaviors. In general, vocalization is the first step to attract females and could be followed by a direct jump by the male, followed by amplexus (e.g., *H. goianus*; Menin et al. 2004) or by a kind of visual or tactile signaling by the female indicating her receptiveness for mating (Hödl 1977; Kluge 1981; Martins and Haddad 1988; Camurugi and Juncá 2013; Landestoy 2013). Despite variations in the courtship behavior within the Cophomantini, none of them exhibit the complex waltz-like interaction herein reported for *B. alvarengai*. However, since our report corresponds to the third available for the genus, other congenerics may share this feature.

Acknowledgments.—We are grateful to Parque Nacional da Serra do Cipó (PNSC) for research support, and Instituto Chico Mendes de Conservação da Biodiversidade (ICMBio) for collecting permit (22170-3). This research was supported by Fundação de Amparo à Pesquisa do Estado de São Paulo (FAPESP, grant 2010/05473-6). FCC was supported by a doctoral scholarship from FAPESP (2009/15712-0). PDPP is supported by a doctoral scholarship from Conselho Nacional de Desenvolvimento Científico e Tecnológico (CNPq). We thank Luke Easton for the courtship drawing, Julián Faivovich for providing valuable comments on the manuscript, and Jay Iwasaki for English revision.

Microhabitat Use of Recently Metamorphosed Mexican Treefrogs in Palo Verde National Park, Guanacaste Province, Costa Rica

Amphibian habitat use is driven by trade-offs between food acquisition, predator avoidance, reproductive behavior, temperature regulation, and water balance (Blomquist and Hunter 2009; Beyer et al. 2010; Köhler et al. 2011). Additionally, the distinct requirements of different life stages of amphibians can result in ontogenetic shifts in habitat use (Semlitsch 2000; Babbitt et al. 2006). Knowledge of habitat use of each life stage is critical for identifying habitat features essential to amphibians so that successful conservation and management strategies can be developed. However, information on the habitat use of all life stages is lacking for most species of amphibians in the tropics.

The Mexican Treefrog (*Smilisca baudinii*) is a nocturnal, arboreal, pond-breeding frog that ranges from southern Texas to southern Costa Rica (Santos-Barrera et al. 2010). Despite being both common and conspicuous throughout much of its range (Duellman 2001), limited information is available documenting *S. baudinii* habitat use, especially for juveniles (Malone 2005). Adult *S. baudinii* occupy habitats near ephemeral bodies of water and are often associated with disturbed sites and secondary forests (Savage 2002). In dry conditions, *S. baudinii* takes refuge under tree bark and in tree holes, in leaf axils of various plants, and in burrows (Meyer and Wilson 1971; Duellman 2001; Savage 2002). *Smilisca baudinii* is known to exhibit explosive breeding in temporary shallow bodies of water cued by heavy rains (Savage 2002).

Juvenile dispersal and habitat use of *S. baudinii* is largely unknown (Malone 2005). It is assumed that post-metamorphic migrations consist of movement from breeding ponds to upland cover sites (Malone 2005). Juvenile habitat use has only been briefly described in a study characterizing the reproductive assemblage of amphibians in a lowland wet forest site in northwestern Costa Rica (Donnelly and Guyer 1994). Donnelly and Guyer (1994) observed four juvenile *S. baudinii* on three different substrate types, two individuals on the grass *Panicum grande* and two individuals on other substrate types not specified. The objective of our study was to determine microhabitat use of recently metamorphosed *S. baudinii* individuals along the edge of the Palo Verde Marsh in Palo Verde National Park, Costa Rica. Our study is the first to describe habitat use of recently metamorphosed *S. baudinii* in tropical dry forest habitat in northwestern Costa Rica.

METHODS

Study site.—We conducted our study at Palo Verde Biological Station (10.3451°N, 85.3387°W) in Palo Verde National Park. The park is located in the lower portion of the Tempisque River drainage basin in Guanacaste, Costa Rica and is composed of semi-deciduous tropical dry forest (Hartshorn 1983). Within the park, a large seasonal freshwater marsh located between the Tempisque River and tropical dry forest serves as an important breeding habitat for at least 13 anuran species (Mora et al. 2012).

Surveys.—We conducted nocturnal transect surveys on 12 June and 13 June 2013 between 2000 and 2430 h. We searched for amphibians along seven 50 x 2 m (by 2 m high) transects laid perpendicular to the Palo Verde Marsh shore for 30 min in each transect (Fig. 1). We surveyed each transect once during the study period. The first ten meters of each transect included aquatic vegtation and standing water and the remaining 40 m included terrestrial habitat. The location for the first transect was randomly selected and each additional transect was separated by 300 m. Transects were representative of both early (N = 4) and late secondary forest (N = 3) that borders the marsh (Fig. 1). For each *S. baudinii* individual sighted, we recorded perch height and microhabitat type (rock, vegetation [narrow-leaf, broad-leaf], wood [fallen logs, tree trunks, and branches], water, and soil).

To estimate the availability of each microhabitat type, every ten meters along the transect (at 0, 10, 20, 30, and 40 m) we rotated blindly several times and dropped a meter stick in a total of four places (for a total of 20 microhabitat samples per transect). The microhabitat types the meter stick touched by this method were used as a random sample of availability of the different microhabitat types (Smith et al. 2003). To determine if microhabitat types were used by *S. baudinii* differently than expected at random, we used a chi-square test.

RESULTS

We observed 103 recently metamorphosed *S. baudinii*, most still showing remnants of a tail from the larval stage. We did not detect any adult *S. baudinii* during transect surveys (although a few adults were observed outside of transect surveys). Mean number (± SD) of *S. baudinii* observed per transect was 15 ± 12 (N = 7). We observed similar abundances of *S. baudinii* in transects located in young secondary forest (14 ± 14, N = 4) and old secondary forest (16 ± 11, N = 3). Vegetation was the most dominant microhabitat available (Vegetation = 53%; Wood = 4%; Leaf litter = 9%; Soil = 21%; Water = 11%; Rock = 2%; Fig. 2). *Smilisca baudinii* metamorphs used microhabitats disproportionately to availability ($\chi^2 = 70.2$, df = 5, $P < 0.001$; Fig. 2). We found the highest percentage of *S. baudinii* on vegetative microhabitat (Fig. 2). Among vegetation types, we observed a higher percentage of *S. baudinii* on broad-leaf plants (83%) than narrow-leaf plants (17%). Average perch height of *S. baudinii* was 34 ± 29 cm (mean ± SD, N = 103). We observed the majority of inividuals on perches less than 50 cm in height (Fig. 3).

DISCUSSION

Our study provides information on habitat use of recently metamorphosed *S. baudinii* in a Costa Rican tropical dry forest during the wet season. We found similar abundances of recently

metamorphosed *S. baudinii* in young and old secondary forest habitats. Recently metamorphosed *S. baudinii* along the edge of the Palo Verde Marsh do not use microhabitat at random but instead, predominantly use vegetation. Our microhabitat-use results are intuitive given the fact that *S. baudinii* is an arboreal species. However, it is notable that we found a higher percentage of use of herbaceous vegetative microhabitat compared to woody plant substrate, and that the majority of *S. baudinii* were perched on broad-leaf rather than narrow-leaf vegetation. We report a lower average perch height than reported in tropical lowland wet forest (approximately 46 cm for juveniles); however, both our study and Donnelly and Guyer (1994) report high variation in perch height. Our observation of a high number of recently metamorphosed *S. baudinii* but no adults in transects likely reflects the seasonality of breeding. Amphibians that have seasonal breeding bouts tend to have little overlap in peak numbers of adults and juveniles (Donnelly and Guyer 1994; Savage 2002).

Pond-breeding amphibians require wetland habitat for breeding and suitable upland habitats for foraging (Semlitsch 2000; Babbitt et al. 2006; Babbitt et al. 2009). Therefore, the connection between wetland and upland habitat is important to facilitate dispersal of juveniles to upland habitat and adults from upland habitat to suitable breeding locations (Pope et al. 2000; Herrmann et al. 2005; Babbitt et al. 2006). The connection between terrestrial and aquatic habitat is not only thought to be important to sustaining pond-breeding amphibian populations but also essential to nutrient transfer and ecosystem function (Regester et al. 2006). Seasonal movements of amphibians can result in production and movement of a large amount of biomass between aquatic and terrestrial habitats. For example, Mora et al. (2012) estimated a seasonal total of 6730 g/day of biomass produced by the marsh in the form of recently metamorphosed frogs in a 300-m stretch of marsh edge in Palo Verde National Park, suggesting that the marsh habitat is a critical component of nutrient transfer and overall function of the surrounding tropical dry forest ecosystem.

In addition to habitat use along the marsh edge, future research should also document habitat use of juvenile and adult *S. baudinii* and other amphibian species in the Palo Verde Marsh in both upland habitat and interior marsh habitat, especially in relation to current active management types (cattle grazing and mechanical removal of *Typha* spp. [Trama et al. 2009]). Our study was limited to a short survey period and one life stage (recently metamorphosed individuals) at the Palo Verde Marsh. Long-term research of multiple life stages over the range of *S. baubinii* is required to make broad generalizations of microhabitat use of *S. baudinii*. Knowledge of habitat use of all life stages of amphibians is important to increase the understanding of the interaction between habitat, behavior, and fitness of these organisms and to work towards developing successful conservation and management strategies.

Acknowledgments.—We thank the staff of Palo Verde Biological Station, especially Sergio Padilla for sharing his knowledge of the herpetofauna of Palo Verde National Park. We thank the Organization for Tropical Studies (OTS) for the opportunity to conduct this study as a part of the Tropical Biology: An Ecological Approach 2013-3 course well as providing supplies and feedback on our study and GIS maps. Thank you to MINAE and SINAC for providing permits to OTS Tropical Biology: An Ecological Approach 2013-3 course, under which this study was conducted.

Use of an Agroecosystem by the Threatened Dart Poison Frog *Andinobates virolinensis* (Dendrobatidae)

Conversion of forested habitats to human land-uses is a primary cause of amphibian declines in tropical regions (Alford and Richards 1999; Vié et al. 2009; Robinson et al. 2013; Kurz et al. 2014). Amphibians may be susceptible to habitat alterations because of their sensitivity to microclimate changes, limited dispersal capacities, and high susceptibility to desiccation (Nowakowski et al. 2013; Robinson et al. 2013; Mendenhall et al. 2014). Previous studies at tropical latitudes have shown that human habitat disturbance generates changes in the structure and composition of amphibian ensembles, promotes the spread of generalists and alien species, and probably leads to local extinctions of species (Urbina-Cardona et al. 2006; Isaacs and Urbina-Cardona 2011; Cortés-Gómez et al. 2013). Given the unprecedented rate of habitat loss in many tropical regions, scientists have focused on assessing the potential of human-altered landscapes, such as agroecosystems, as an alternative approach to biodiversity conservation (Schroth et al. 2004; Somarriba et al. 2004).

Shaded coffee plantations resemble forest-like habitats in terms of vegetation structure and density, including several levels of vertical stratification of arboreal elements and a complex canopy that modulate the microclimates of the coffee understory, which are likely to be critical to maintain levels of biodiversity comparable with those found in adjacent native forests (Perfecto et al. 1996; Moguel and Toledo 1999; Somarriba et al. 2004; Philpott et al. 2008; Urrutia-Escobar and Armbrecht 2013). In Colombia, shaded coffee plantations are known to harbor a high species richness of birds, bats, arthropods, and plants, including forest species (Castaño et al. 2004; Peraza et al. 2004; Sánchez-Clavijo et al. 2007; Urrutia-Escobar and Armbrecht 2013). However, current knowledge about how natural populations of Colombian amphibians interact in these agroforestry systems remains poorly understood.

A first approach suggests that the herpetofauna in agroecosystems (mainly on coffee and banana plantations) of the Colombian Coffee Belt are less biodiverse than nearby forests, grasses, and even human infrastructures (Hoyos-Hoyos et al. 2012). In contrast, studies from montane landscapes in Mexico suggest that the capacity of shaded coffee plantations to support amphibian species are related to the proportion of canopy cover and patch size (Pineda and Halffter 2004; Pineda et al. 2005). It appears that a decrease in patch area and canopy cover results in a reduction of the structural complexity and availability of microhabitats for amphibian species (Pineda and Halffter 2004). In this sense, understanding how species maintain viable populations in modified agricultural systems is urgent for undergoing integrative management and conservation strategies (Perfecto et al. 1996, 2003, 2007; Anaya-Rojas et al. 2010).

Andinobates virolinensis, commonly referred to as the Santander Dart Poison Frog, is a diurnal, aposematic dendrobatid leaf-litter inhabitant. This species belongs to the *Andinobates bombetes* species group (Brown et al. 2011), and like many other species in the clade it is restricted to disjunct forest fragments within the 1300–2300 m elevation range (Amézquita et al. 2013). Most of the altitudinal distribution of these species occurs within the Colombian coffee belt, between 1000–2000 m elevation (Rueda-Almonacid et al. 2006; Amézquita et al. 2013). The forests within this elevational belt have been severely modified from extensive cattle ranching and intensive agricultural activities that include traditional and exotic crops, as well as coffee production (Rueda-Almonacid et al. 2006; Amézquita et al. 2013; Luna-Mora and Guayara-Barragan 2014). Because the elevational range of frogs in the *bombetes* group overlaps with intensive agricultural production, they face serious conservation threats (Amézquita et al. 2013).

Andinobates virolinensis has a restricted range along the northwestern slope of the Cordillera Oriental of Colombia (Brown et al. 2011). The species inhabits primary and secondary Andean forests between 1700–2000 m, which are characterized by the presence of oaks (*Quercus humboldtii* and *Trigonobalanus excelsa*), arums, and abundant epiphytes (Ruiz-Carranza and Ramírez-Pinilla 1992; Stuart et al. 2008; Valderrama-Vernaza et al. 2010). *Andinobates virolinensis* is listed as Endangered B1ab (iii) according to the IUCN Red List because the species' estimated extent of occurrence is less than 5000 km^2, it is known to exist at no more than five confirmed locations, and the population trend is apparently decreasing due to a continuous decline in the quality and extent of its natural habitat (Amézquita and Rueda-Almonacid 2004).

Here, we report the first record of a natural population of *A. virolinensis* inhabiting a young plantain plantation and a mature mixed culture of shaded coffee and plantain trees in the Serranía de los Yariguíes, Santander Department, Colombia. These traditional cultures have the structural and vertical complexity features of a traditional polyculture system *sensu* Moguel and Toledo (1999). We provide preliminary data about habitat use and population density in these human-managed systems. This information is crucial to improve our understanding about natural history traits of the species and provide an opportunity to evaluate the impact of human activities on *A. virolinensis* populations.

Materials and methods.—The study area is located in the northwestern slope of the Colombian Cordillera Oriental, in the municipality of San Vicente de Chucurí, Vereda La Colorada

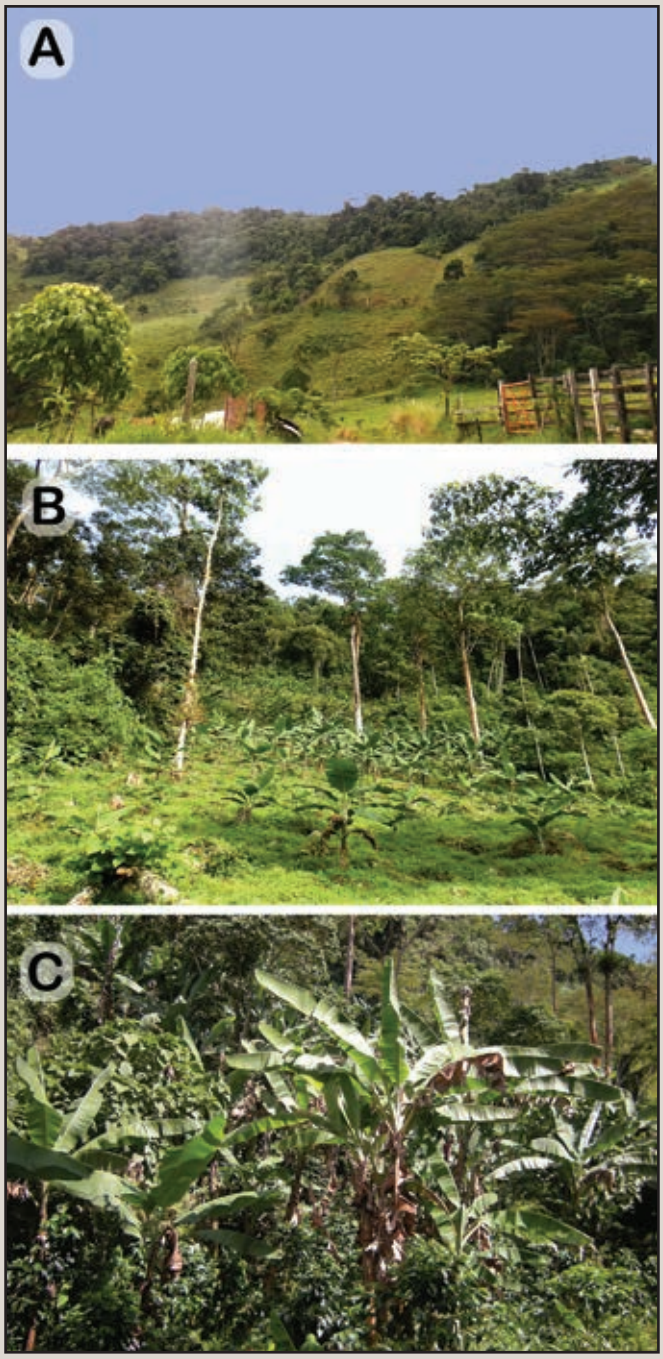

FIG. 1. Habitats sampled in the study site. A) Disturbed Andean cloud forest patch. B) Young plantain culture with sparse native shade. C) Mature plantation with a mix of plantain and coffee with dense native shade.

(Santander Department, 6.784°N, 73.468°W, 1450 m elev.). The area lies within the Distrito de Manejo Integrado Serranía de los Yariguíes, adjacent to Parque Nacional Natural Serranía de los Yariguíes. Historically, this zone has two peaks of rain (March to June and August to November), with a mean annual temperature of 21°C and a mean annual rainfall of 1928 mm (Hijmans et al. 2005).

We identified three habitats with different anthropogenic disturbance in the study area (Fig. 1). The first habitat (H1, Fig. 1a) consisted of a cloud forest patch of nearly 1 km^2 area, disturbed by selective cutting and surrounded almost completely by cattle-grazing grasslands. Structurally, this forest fragment is complex, with a dense canopy of trees up to 30 m high, dominated by trees of the genera *Erythrina* (Fabaceae), *Nectandra* (Lauraceae), and *Cordia* (Boraginaceae). Bromeliads were predominant on large trees. The second habitat (H2, Fig. 1b) corresponded to a young (<1 yr old) plantain plantation (*Musa* spp.) with a sparse canopy of native tree (15–25 m height) species (primarily *Erythrina* spp.) with abundant bromeliads. The third habitat (H3, Fig. 1c) was a mature mixture of shade grown (>5 yr old) plantain trees (*Musa* spp.) and coffee trees (*Coffee arabica*) with a dense canopy of *Erythrina* trees with abundant bromeliads.

We conducted fieldwork from April to August 2012, which consisted of three field surveys. Frog sampling was conducted using two standardized methods: visual encounter surveys (Crump and Scott 1994) and plot or quadrant sampling (Jaeger and Inger 1994), as well as opportunistic observations. Surveys were carried out during the day, between 0800–1800 h.

During the first sampling period on 5 April 2012, we conducted visual encounter surveys along randomly selected transects covering the whole extent of the study area (i.e., H1, H2, and H3). Surveys were carried out during the day by five persons looking carefully for *Andinobates virolinensis* in all potential microhabitats available during a period of three days, totaling 120 h of sampling effort (24 h/person). Because of the low encounter rate of frogs in the first habitat (H1) during this sampling period, we excluded this area from further surveys.

We performed two additional survey periods on 23 May 2012 and 28 August 2012, each of three days, using plot or quadrant sampling. This method provides fairly accurate estimates of density and allows comparisons between studies and sites (Allmon 1991; Rödel and Ernst 2004). For this, we set up 15 quadrants (8 x 8 m) on the floor of each habitat for a total of 960 m^2 of sampled area. During every sampling period, each plot was visited once for about 1.5 h by two persons moving side-by-side, checking for frogs in all potential microhabitats available. Special attention was paid to potential hiding places and reproductive sites. To avoid recounting of individual frogs, each frog was captured by hand and kept in plastic bags with moist leaf litter. Then, the frogs were released nearby the same area at the end of the plot survey.

For estimates of relative density of adults, only the data obtained by plot or quadrant sampling were considered. The relative density was calculated as the number of individuals per total area of sampling, averaged for the period of sampling to obtain a mean density for each habitat. Relative density between habitats was compared with a Mann-Whitney U test.

The microhabitat usage was assessed for all observed frogs, including data obtained from the two sampling methods (e.g., visual encounter surveys and plot or quadrant sampling), plus those collected during opportunistic encounters. For every frog seen, we recorded the type of habitat, substrate (e.g., rock, leaf-litter, vegetation, wood, etc.), height above ground, distance to potential tadpole deposition sites, and activity (feeding, calling, amplexus, nursing, or jumping).

Bromeliad abundance was estimated by counting the number of bromeliad ramets (i.e., clusters of individuals) in each plot, irrespective of substrate (ground, tree trunks and branches). Bromeliad abundance between habitats was compared with a Mann-Whitney U test. To test the relationship between number of frogs and bromeliad abundance per plot we conducted a Spearman's rank correlation.

Results.—During fieldwork we recorded 54 individuals of *Andinobates virolinensis* (24 adults, 4 juveniles, and 26 tadpoles on

FIG. 2. The dart poison frog, *Andinobates virolinensis*. (A) Male parents transport their offspring attached to the back, to phytotelmata in bromeliads. Male nurse carrying (B) one, (C) two, and (D) four tadpoles simultaneously.

the nurse frogs' backs) as follow: 2 males in the first habitat (H1); 7 males, 1 female, 3 juveniles, and 5 tadpoles in the second habitat (H2); 10 males, 4 females, 1 juvenile and 21 tadpoles in third habitat (H3). Based on the results from the plot sampling, we calculated a relative density of 42 ± 15 adult individuals per ha in the second habitat (H2) and 73 ± 15 adult individuals per ha in the third habitat (H3).

The density of adult individuals differed significantly among habitats (Mann-Whitney, $Z = -2.16$, $P = 0.026$), and habitat H3 exhibited the highest density. The abundance of bromeliads found in each habitat varied significantly (Mann-Whitney, $Z = -1.92$, $P = 0.047$). H3 presented the highest values of bromeliads abundance. As expected, there was a relationship between number of adult frogs and bromeliad abundance in each plot (Spearman, $R = 0.88$, $P < 0.001$).

The spatial distribution of frogs within this agroecosystem was not homogeneous. Instead, the frogs were always found associated with areas adjacent to large native trees with abundant and large bromeliads. No frogs were found within treeless areas, or even in areas with trees lacking large bromeliads. Frogs were recorded mainly in moist rock and tree-root cavities covered with leaf-litter, no more than 3 m away from trees' stems. Two adult males were recorded calling inside moist rock cavities with small water pools. We observed 12 male nurse frogs carrying 1–4 tadpoles at a time (Fig. 2). The tadpoles were at the same stage of development.

Some males partially used plantain and coffee plants only to walk onto adjacent native trees with bromeliads. No tadpoles were observed in the small bromeliads located on the trees below 8 m height or on ground bromeliads. Although bromeliads above 15 m height were not searched for tadpoles, we observed 3 male nurse frogs transporting tadpoles from the ground to bromeliads between 10 and 15 m. During the fieldwork, we did not find eggs laid or frogs engaged in courtship. However, the fact that males were found calling between rock cavities where small water bodies form between the litter and that several male nurse frogs were also found transporting tadpoles near these water pools suggest that these sites might represent a potential microhabitat for females to deposit their eggs.

Discussion.—The density of *Andinobates virolinensis* was significantly lower in the habitat corresponding to a young traditional plantain plantation (H2) than in the habitat corresponding to a mature mixed plantation of coffee and plantain (H3). In this

sense, the low number of bromeliads in H2 relative to H3, could limit its potential to harbor high population densities. Similar results have been documented for *A. virolinensis* inhabiting forested areas, where the density of adult males is apparently related to density of bromeliads for tadpole deposition (Cáceres 2007). These results agree with those from other studies in the dart poison frog *Andinobates bombetes* (Vargas-Salinas and Amézquita 2013) and *Oophaga pumilio* (as *Dendrobates pumilio*, Donnelly 1989; Pröhl 2002), which indicate that the density of reproductive resources, such as bromeliads, represent a good predictor of density of adult frogs. In contrast, in *A. opisthomelas* (as *Ranitomeya opisthomelas*) there is no apparent association between density of frogs and number of bromeliads (Ríos et al. 2011).

It seems that remnant native trees with bromeliads represent key features to the presence of the species in this agroecosystem. Moreover, it is possible that density differences between the studied habitats could be influenced by canopy cover of remnant native vegetation, as well as percentage of leaf litter, leaf litter moisture, depth of soil cover, and leaf litter mass. Remnant native vegetation are considered keystone structures of altered landscapes because of their capacity to harbor native species of fauna and their contribution to ecosystem functioning, representing an invaluable feature that must be actively protected and managed (Manning et al. 2006; Sekercioglu et al. 2007; Fischer et al. 2010; Robinson et al. 2013; Mendenhall et al. 2014).

The presence of juveniles, females, calling males, and nurse males carrying tadpoles to bromeliads indicates that this population of *Andinobates virolinensis* is successfully breeding within this agroecosystem. This can be explained by the persistence of suitable microhabitats provided by native trees with high abundance of bromeliads, tree-root cavities, leaf litter, and moist rock cavities, which provide adequate conditions for shelter, sites for calling, mating, and egg-laying, as well as phytotelmata for tadpole development. The fact that these frogs can breed in these traditional plantations is important because it increases the conservation and management opportunities for the species. In this sense, resource management activities (e.g., supplementation of reproductive resources, like bromeliads or artificial pools) may play a critical role in the management of populations where these resources are limited.

Recent studies suggest that forest conversion to coffee plantations could represent a primary threat for species of the *bombetes* group (Rueda-Almonacid et al. 2006; Amézquita et al. 2013; Luna-Mora and Guayara-Barragan 2014). In fact, such agroecosystems have been thought of as unsuitable habitats for *Andinobates tolimensis* (Bernal et al. 2007). However, traditional shaded coffee plantations, such as those in most of Santander Department (Colombia), are complex agroforestry systems that maintain a high biodiversity, including migratory and threatened species of birds (Peraza et al. 2004; Sánchez-Clavijo et al. 2008), bats (e.g., Castaño et al. 2004), and frogs (this study). However, it is still unclear whether these plantations are suitable forest-like habitats for native species or if they simply represent secondary habitats to avoid the deleterious effects of habitat loss, as recognized by Faria et al. (2007) for cacao-producing landscapes in Brazil.

The natural history traits reported in the studied population of *Andinobates virolinensis* differed from other studied populations. These differences could be the result of different selective pressures or a bottleneck effect in this isolated population, as proposed by Lima and Eterovick (2013) in a population of the dendrobatid frog *Ameerega flavopicta* in Brazil. Under both scenarios, the surviving individuals of the population happened to be phenotypically successful in the novel altered habitat. Nevertheless, additional studies are necessary to test these hypotheses. In general, the results of this study show that our understanding of the long-term impacts of environmental change on populations of *A. virolinensis* is still in an early stage of understanding.

Agroecosystems can be viewed as complementary habitats in a broader conservation scheme in which fragments of native forests represent the keystone in regional conservation efforts (Perfecto et al. 1996; Somarriba et al. 2004; Perfecto et al. 2007). Unfortunately, under current management practices, the habitat quality of shaded coffee plantations in Colombia is likely to decline over time due to agricultural and pastoral land-use intensification, which may have a negative effect on biodiversity (Rojas et al. 2012; Urrutia-Escobar and Armbrecht 2013). In this sense, working with agriculture practitioners can both promote local economic development and species conservation initiatives.

Acknowledgments.—Financial and logistic support was provided by Asociación Colombia Endémica. We thank R. Saporito, S. Lötters, M. Torres, M. P. Ramírez, G. Köhler, and two anonymous reviewers for suggestions and comments on the manuscript. A. Celis kindly performed the taxonomic identification of plant species. E. Meneses provided assistance gathering data and helping as field guide. This project was partly funded by Asociación Colombiana de Herpetología.

Upstream Dam Passage and Use of an Eel Ladder by the Common Watersnake (*Nerodia sipedon*)

Seasonal movement patterns, an important aspect of the ecology and life history of the Common Watersnake (*Nerodia sipedon*), may be altered in areas of anthropogenic habitat modification (Roe et al. 2006; Roth and Greene 2006). Reservoir dams represent a common and widespread habitat modification and can influence movement patterns of reptiles in riverine and riparian habitats (Hunt et al. 2013). Common Watersnakes often move along river corridors (Pattishall and Cundall 2008) but also disperse along riparian corridors (Tiebout and Cary 1987). Although reservoir dams are prevalent within riverine systems (Graf 1999; Poff and Hart 2002), little is known about how dams affect movement patterns of Common Watersnakes. Dams are documented barriers to upstream movement of many fish species (Liermann et al. 2012), and fish passage facilities have been installed on some dams (Schilt 2007; Roscoe and Hinch 2010). Passage facilities are used occasionally by non-target aquatic species, such as crustaceans, lampreys, and turtles (Meehan 2003; Keefer et al. 2013), but we know of no previous studies that have documented upstream passage by Common Watersnakes.

In this study, we report the use of an eel ladder (a fish passage facility targeting upstream migrant American Eels) by Common Watersnakes in the lower Shenandoah River, a large tributary of the Potomac River drainage, USA. Our study objectives were to document dam passage and the use of an eel ladder by Common Watersnakes, and examine the association of passage events with environmental variables. This study is relevant to understanding movements of Common Watersnakes at a dam tailwater and the potential for dam passage in a regulated river.

Methods.—The Shenandoah River drains approximately 7870 km^2 of the Valley and Ridge and Blue Ridge physiographic provinces in Virginia and West Virginia (Jenkins and Burkhead 1994). A 296-m wide by 5-m high low head hydroelectric dam is located on the lower Shenandoah River at Millville, West Virginia (95 m elev.; 39.2689°N, 77.7820°W; Fig. 1). Millville Dam is approximately 9 river km upstream from the confluence of the Potomac and Shenandoah rivers. A fish ladder, designed for upstream dam passage of 15–80 cm total-length American Eels is located on the western end of Millville Dam (Welsh and Liller 2013; Fig. 2). This 11-m long eel ladder is a covered stainless steel sluice (13 cm depth x 41 cm width) with a 50° slope. Inside the ladder, a peg board of three vertical rows of 5.1-cm diameter ABS plastic pipes provides climbing substrate, which is designed for serpentine movements of American Eels (Welsh and Liller 2013). The eel ladder is typically removed in November and reinstalled the following year during late spring to early summer (Table 1). Removal of the eel ladder, which occurs at the discretion of the hydropower company, is a preventative measure to reduce ladder damage from large woody debris associated with high river discharges during late fall through early spring.

To obtain data associated with ladder passage events, American Eels and Common Watersnakes are collected and counted from a net bag (3.2 mm stretched mesh) on the upstream end of the ladder. Also, an infrared-triggered eel ladder camera, which photographs each American Eel or non-target species that passes through the ladder, is used for monitoring passage events. Individuals are photographed when passing through a plexiglass chamber, which is spliced into a PVC pipe leading from the top of the ladder. Using digital photographs (date and time stamped) from the eel ladder camera, we obtained data on counts of

individuals, timing of passage, and head width measurements using photogrammetric methods with digital imaging software (Welsh and Aldinger 2014).

To examine environmental variables associated with passage events of Common Watersnakes, we calculated mean values and recorded ranges of river discharge (m^3s^{-1}), lunar illumination, and water temperature (°C). River discharge data were obtained from a U.S. Geological Survey gauge at Millville, West Virginia. Lunar illumination, measured as fraction of the moon face ranging from 0 (new moon) to 1 (full moon), was calculated from an astronomical algorithm (Meeus 1991). Water temperature at Millville Dam was recorded with a StowAway Tidbit Temp Logger (Onset Computer Corporation).

Results.—During 2007–2014, the Millville Dam eel ladder passed 18,215 American Eels and 12 Common Watersnakes (Table 1). Passage events of Common Watersnakes occurred in 2007, 2008, 2012, 2013, and 2014. Eleven individuals passed during summer months (28 June–August 28), and one individual passed during fall on 5 October 2013. During 2007–2008, four Common Watersnakes were collected from the net bag on the terminal end of the eel ladder and were released without measurement. From 2012–2014, eight Common Watersnakes were photographed by the eel ladder camera (Fig. 3), and head width was measured for seven individuals (mean ± SE = 18.5 mm ± 0.96, range 14.8–21.6 mm). Seven Common Watersnakes passed during daylight hours between 0628–1726 h. One Common Watersnake, however, entered the ladder at night and was photographed 97 times from 0337–0810 h, a time period that included passage of 18 American Eels (Fig. 3). Based on timing of passage and the number of photographs for each individual, most watersnakes quickly passed through the plexiglass photographic chamber of the ladder.

River discharge, water temperature, and lunar illumination were recorded for passage events of 12 common watersnakes. Watersnakes used the eel ladder during periods of low river discharge (mean ± SE = 24.5 m^3s^{-1} ± 1.4, range 16.3–32.6 m^3s^{-1}). During the time period of 2007 through 2014, the annual mean ± SE of daily river discharge values at Millville Dam was 62.0 m^3s^{-1} ± 3.8 (range 13.2–606.0 m^3s^{-1}). Common watersnakes used the eel ladder during a narrow range of water temperatures (mean ± SE = 26.5°C ± 0.53, range 23.5–30.9°C; Table 1). Data on lunar illumination associated with passage events were bimodal, with four events at a new moon (lunar illumination ranged from 0.00–0.06), five at a full moon (0.94–1.0), two near a waxing quarter moon (0.43–0.52), and one near a waning quarter moon (0.43).

Discussion.—Our data documented the use of an eel ladder by Common Watersnakes at Millville Dam on the lower Shenandoah River, West Virginia. It is not known if individuals entered the ladder for sheltering, foraging, upstream movement, or alternative reasons. A total of 12 passage events during an eight-year period does not suggest the eel ladder is an effective method of reducing a "dam barrier effect" on upstream movements of watersnakes. Our study, however, is the first to report that Common Watersnakes will occasionally use an eel ladder, which allows a more direct route of dam passage relative to travel along riparian corridors.

Common Watersnakes may have used the eel ladder as a thermal refuge or as a cover shelter to avoid predation and human risks. The eel ladder, which is a covered stainless steel sluice, may attract Common Watersnakes during daylight hours because of its warm conductive surface. Also, the tailwater of Millville Dam

is primarily bedrock with relatively few large cobbles or boulders available for cover objects, thus Common Watersnakes may use the ladder as a cover shelter to reduce predation risk (Gregory 2009). Furthermore, angling occurs commonly at the Millville Dam tailwater, and because Common Watersnakes often exhibit escape behavior when approached by humans (Cooper et al. 2008), the eel ladder may be used as a shelter to avoid perceived threats from humans.

Ladder use and dam passage of Common Watersnakes occurred across a narrow range of river discharges and water temperatures. Most passage events occurred when river discharge was low (< 33 m^3s^{-1}), which may be explained by either reduced movements during high river discharges or the inability of Common Watersnakes to find the ladder base when the dam spillway is inundated by high water levels. Eleven of 12 passage events occurred during summer, with water temperatures ranging from 24.7 and 30.9°C, whereas one passage event during fall occurred at 23.5°C. Use of the ladder during summer is consistent with expected times of increased activity and movement, because Common Watersnake activity is positively correlated with water temperature (Andreadis 1997; Finkler and Claussen 1999), and the preferred body temperature of the Common Watersnake has been reported at approximately 28.0°C (Lillywhite 1987; Lutterschmidt and Reinert 1990).

Lunar phase was associated with ladder use by Common Watersnakes, where most passage events occurred on or near new moons or full moons. It is unclear, however, if illumination associated with moon phase influenced behavior or if the activity of these Common Watersnakes was controlled by an endogenous circalunar clock. Watersnakes and many other snakes are often less active on or near the full moon (Madsen and Osterkamp 1982; Houston and Shine 1994; Kronfeld-Schor et al. 2013), although the terrestrial Florida Cottonmouth (*Agkistrodon piscivorus conanti*) has been shown to increase nocturnal foraging activity near the full moon (Lillywhite and Brischoux 2012). Andreadis (1997) found that foraging activity of Common Watersnakes increased during low levels of lunar illumination near new or waxing moons. Nocturnal activity during periods of reduced moonlight may assist Common Watersnakes with capturing prey as well as reduce predation risk (Andreadis 1997). In our study, however, most individuals used the ladder during daylight hours, suggesting that a circalunar biorhythm may influence activity associated with moon phase.

Agostinho et al. (2012) found that fish ladders may attract fish predators. Common Watersnakes are piscivorous (Raney and Roecker 1947) and are known to eat American Eels (Gibbons and Dorcas 1994). Thus, it is possible that high abundances of American Eels at the base of the eel ladder or eel scent from the eel ladder attracts Common Watersnakes. However, as previously emphasized, most Common Watersnakes used the eel ladder during daylight hours, and American Eel passage occurred primarily at night. One Common Watersnake that used the ladder at night remained in the photographic chamber for 4.8 h, a time period when 18 American Eels passed through the ladder, but it is unknown if this individual consumed American Eels when inside the eel ladder.

This study demonstrated that an eel ladder can aid upstream dispersal of Common Watersnakes. It is not known, however, if the watersnakes were using the eel ladder for the purpose of upstream passage. Use of the eel ladder may benefit Common Watersnakes by allowing upstream access within the river corridor. However, once upstream of the dam, individuals would likely require the riparian corridor to reaccess the dam tailwater. Our data on eel ladder use and dam passage are relevant to understanding activity and movement patterns of Common Watersnakes in the vicinity of dams.

Eye Color and Chin Pattern in the Turtle *Graptemys pseudogeographica* in the Calcasieu River Drainage of Louisiana, with Comparison to Adjacent Drainages

Eye coloration is a characteristic of freshwater turtles that is little noted in field guides and formal descriptions of taxa, probably because it cannot be assessed in preserved specimens. In the genus *Graptemys* (map turtles and sawbacks), three predominant patterns of eye coloration occur (Lindeman 2013): a) a yellow or b) white iris, bisected by a black stripe, and c) a white iris without a bisecting stripe. The striped white iris typifies *caglei*, *ouachitensis*, *sabinensis*, and *versa*, while southern populations of *pseudogeographica* (the subspecies *kohnii*) are most frequently reported to have white irises without bisecting stripes. Yellow irises with black stripes typify populations of the nominate northern subspecies of *pseudogeographica* as well as the remaining species, *barbouri*, *ernsti*, *flavimaculata*, *geographica*, *gibbonsi*, *nigrinoda*, *oculifera*, *pearlensis*, and *pulchra*.

Graptemys species all have yellow to light-orange stripes, spots, and blotches against a darker ground color on the head, neck, and limbs. Three predominant patterns of light chin markings occur and are used as reliable diagnostic characteristics of species (Carr and Marchand 1942; Cagle 1952, 1953a, b, 1954; Haynes and McKown 1974; Lovich and McCoy 1992; Vogt 1993; Ennen et al. 2010b; Lindeman 2013): a) three spots, one anterior and medial and the other two, which are often elongated, below the angles of the jaw (*ouachitensis*, *pseudogeographica*, *versa*); b) a medial longitudinal blotch or stripe and two spots under the angles of the jaw, also often elongate (*ernsti*, *geographica*, *gibbonsi*, *pearlensis*, *pulchra*); and c) a transverse chin bar, essentially a curving stripe along the lower margin of the chin (*barbouri*, *caglei*, *flavimaculata*, *nigrinoda*, *oculifera*, and *sabinensis*).

In a published conference abstract, Jackson and Shively (1983) briefly described distinctive characteristics of *Graptemys pseudogeographica* from the Calcasieu River drainage, which drains portions of seven parishes in southwestern Louisiana. In particular, the authors described two distinctive characters: 1) dark pigmentation of the entire iris, causing the irises to appear black, and 2) variation in the chin pattern, with individuals having both three-spot and barred patterns on the chin. Chin patterns were thus a mix of two of the predominant patterns used as diagnostic features of many congeners.

During wide-ranging freshwater turtle survey efforts on the Calcasieu drainage and its two adjacent drainages, the Sabine to the west and the Mermentau to the east, we encountered *G.*

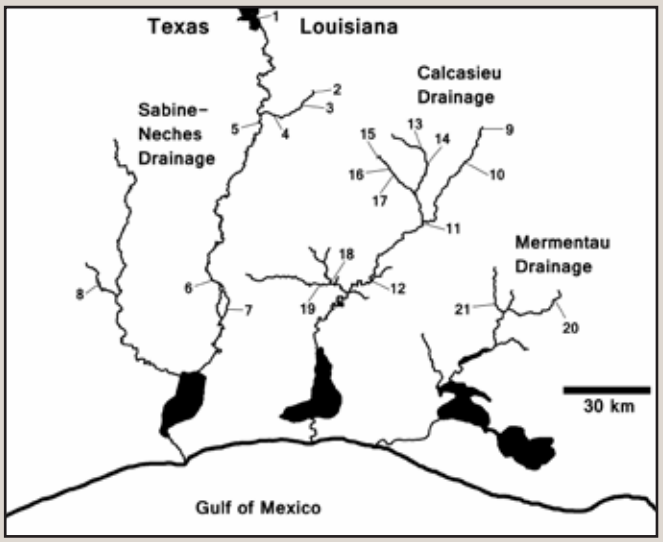

FIG. 1. Trapping and photographic localities for *Graptemys pseudogeographica* on the Sabine-Neches, Calcasieu, and Mermentau drainages of southwestern Louisiana and southeastern Texas. Numbers correspond to sites listed in Appendix I.

FIG. 2. Three *Graptemys pseudogeographica* exhibiting the dark-brown iris found in most specimens caught in the Calcasieu drainage. Top, juvenile, Whiskey Chitto Creek near Hwy. 26 crossing in Allen Parish, Louisiana. Middle, female, midline plastron length 209 mm, West Fork Calcasieu River at Sam Houston Jones State Park in Calcasieu Parish, Louisiana. Bottom, female, midline plastron length 187 mm, Serpent Bayou <1 km from its confluence with the mainstem Calcasieu River in Calcasieu Parish, Louisiana.

pseudogeographica at several sites. Here we report on patterns of iris coloration and chin patterns for specimens in these drainages to quantify the patterns noted by Jackson and Shively (1983) and make comparisons among the adjacent drainage populations.

Study Areas and Methods.—We surveyed turtles in the Calcasieu drainage in four parishes, the Sabine drainage in four parishes, and the Mermentau drainage in four parishes (Fig. 1). The Calcasieu and Sabine drainages have a mix of very low-elevation downstream reaches—less than 1 m above sea level (asl), according to Google Earth—that are uniformly deep and sluggish, contrasting with upstream reaches that have gradients that promote a riffle-run organization with currents that maintain abundant sandbars. The entire Mermentau drainage is uniformly deep and sluggish, with surface levels that are <1 m asl throughout the reaches we surveyed, according to Google Earth.

Turtles were captured in 2010–2013 using fykenets (Vogt 1980), basking traps (Lindeman 2014; Selman et al. 2012), and baited hoop nets (Legler 1960), with occasional opportunistic dipnetting or hand capture, mostly of juveniles. Eye color and chin pattern of captured *Graptemys pseudogeographica* were photographed with zoom or macro lenses. Turtles were marked on their marginal scutes (Cagle 1939) to avoid double-counting; however, no recaptures were registered for the species, even when trapping was conducted over several days at some sites. Additional photos of captured *G. pseudogeographica* were also available from previous studies (Shively and Vidrine 1984; Shively and Jackson 1985). Additional lower-resolution evidence for eye color and chin pattern was sometimes available from photographs of basking turtles taken using zoom lenses (up to 45x) on tripod-mounted cameras between 2008 and 2013. Based on geographic distances between sites, sampling dates, and details of turtles visible in photos, we feel confident that basking photos did not contain any duplicate photos of the same individual.

Fisher's exact tests were used to compare the Calcasieu drainage with its two adjacent drainages for frequency of iris and chin characters in *G. pseudogeographica*. For these analyses, dark-brown irises were compared against a combined category for lighter colors and chin pattern was scored as complete bar, three spots or spot-line-spot, or intermediate (see below).

Results.—A total of 46 *G. pseudogeographica* were captured and photographed for iris color, with 34 of these also photographed for chin pattern. Thirty-two other individuals photographed during basking surveys had discernible iris color and 7 of these showed discernible chin patterns in their photos.

FIG. 3. Dark-brown irises evident in two basking *Graptemys pseudogeographica* photographed in the Calcasieu drainage. Top, female, Bundick Creek at Morrow Bridge Rd. in Allen Parish, Louisiana. Bottom, male, Calcasieu River at at Hwy. 10 crossing in Allen Parish, Louisiana.

PHOTOS BY PVL

FIG. 4. Two *Graptemys pseudogeographica* from the Sabine drainage exhibiting a light-yellow iris suffused with gray speckling along the outer margins with prominent horizontal black bars bisecting the iris, as seen in all adult females of the Sabine drainage specimens. Top, female, midline plastron length 233 mm, East Sabine River upstream of Niblett's Bluff, Calcasieu Parish, Louisiana. Bottom, female, midline plastron length 192 mm, Sabine River upstream of Palmer Lake Rd. boat ramp, Beauregard Parish, Louisiana/Newton County, Texas.

Localities for these encounters in the three drainages are shown in Fig. 1 and listed with character data in Appendix I.

At six sites on the Calcasieu drainage, we captured 32 *G. pseudogeographica*, of which 30 (94%) had dark-brown irises, with a black horizontal bar bisecting each iris that was visible upon close inspection (Fig. 2). A hatchling and a juvenile female had lighter, barred irises (white in the hatchling, light yellow in the female) that were suffused with speckled gray along the outer rims in both.

Photographs of basking turtles showed evidence of dark-brown irises for 14 *G. pseudogeographica* at 7 sites throughout the Calcasieu drainage (Fig. 3). No other eye color pattern was evident in any basking photographs of the species from the Calcasieu drainage.

In the Sabine drainage, we captured 14 total *G. pseudogeographica* at 4 sites. None exhibited a dark-brown iris. The pattern observed in 8 of 9 females, including the 7 largest females (PL range 116–233 mm), was a light-yellow iris suffused with speckled gray along the outer rim, with a wide horizontal black bar bisecting the iris (Fig. 4). The second-smallest female (PL 137 mm), 3 males, and 2 juveniles likewise had gray speckling around the outer rim of the iris, but the background color of the iris was white rather than light yellow. Black bars bisected the iris in all but one of these 14 turtles; an adult male lacked iris stripes. No *G. pseudogeographica* were among 435 total turtles we captured in the Mermentau drainage (including 326 individuals of a congener, *G. sabinensis*).

Sixteen basking *G. pseudogeographica* were photographed at six total sites in the Sabine drainage. None exhibited a dark-brown iris. Eight females, all of which appeared to be of adult size, appeared to have the yellow and gray, black-barred iris type shown in Fig. 4, while the remaining female—the only clearly juvenile female—had a white, black-barred iris. In Lindeman (2013), two of the adult females appear in Plate J5 and the juvenile female appears in Plate J1. Three unsexed juveniles and three of the four males had white irises with black bars, while the remaining male had a white iris without a bar. The unbarred male appears on the back jacket cover of Lindeman (2013). Two basking *G. pseudogeographica* were photographed at separate sites in the Mermentau drainage. A published photograph of one individual from the Mermentau drainage shows a white iris without a horizontal black bar (Ilgen et al. 2014), although additional photographs of the same turtle suggest it may have had a very thin black horizontal bar through each iris (PVL, unpubl. photos). The other photograph from the Mermentau drainage is of poorer quality due to greater distance of the camera from

FIG. 5. Variable chin patterns of *Graptemys pseudogeographica* in the Calcasieu drainage. Top, three-spot pattern with elongate side spots, adult female, 209 mm midline plastron length. Bottom, transverse chin bar, adult female, 195 mm midline plastron length. Both specimens from the vicinity of Sam Houston Jones State Park, near the confluence of the Houston River with the West Fork Calcasieu River.

the turtle, but shows a white iris with no evidence of a horizontal bar. Combining captured turtles and turtles photographed while basking, the difference in iris color between the Calcasieu drainage (46 dark brown vs. 2 lighter) and its two adjacent drainages (0 dark brown vs. 30 lighter) was highly significant (Fisher's exact test, $p < 0.0001$).

In the Calcasieu drainage, we photographed chin pattern for 22 of the 32 captured turtles (Fig. 5). Nine exhibited a round medial spot at the point of the chin and elongate spots on either side, under the angles of the jaw; 1 had two elongate spots on either side and a central spot that was merged with a neck line; 9 had transverse chin bars instead of spots; and 3 had intermediate patterns. Intermediate patterns were essentially transverse chin bars that had small gaps near the point of the chin (on both sides in 2 turtles, suggestive of 3 elongate spots that almost merged into a bar; on the left side only in the other turtle, suggestive of an incomplete bar; all patterns labeled intermediate lacked the several intervening light lines or whorls between the medial and side spots that were typical of the three-spot pattern). There was no ontogenetic component evident in the variation, as the chin bars were exhibited by 4 adult females, 1 juvenile female, 1 unsexed juvenile, and 3 hatchlings. Chin pattern was visible and clearly discernible in only two photographs of basking individuals in the Calcasieu drainage, both of which had the three-spot pattern.

In the Sabine drainage, chin pattern was photographed for 12 of the 14 turtles we captured. Nine individuals exhibited a three-spot chin pattern, two had the anterior, medial spot elongated as a longitudinal blotch, and one had an incomplete bar, with a small gap on the right side near the point of the chin. In photographs of basking individuals, three individuals exhibited the three-spot pattern. Likewise, both basking individuals photographed on the Mermentau drainage exhibited the three-spot chin pattern. Combining captured turtles and turtles photographed while basking, the difference in chin pattern between the Calcasieu drainage (12 three-spot or spot-line-spot patterns, three intermediate patterns, and nine complete bars) and its two adjacent drainages (16 three-spot or spot-line-spot patterns, one intermediate pattern, and 0 complete bars) was highly significant (Fisher's exact test, $p = 0.0037$).

Discussion.—Almost all of the *G. pseudogeographica* captured in the Calcasieu drainage exhibited dark-brown irises bisected by black lines and all basking specimens photographed on the Calcasieu drainage were consistent with the same coloration. No specimens from the two adjacent river drainages had dark-brown irises and the coloration has never been reported from other localities, thus iris color appears to be a highly consistent diagnostic feature of Calcasieu populations. Localities exhibiting the dark-brown iris that are reported herein encompass virtually the entire range of the species within the drainage (Fig. 1 and Appendix I), thus the dark-brown color is not merely a local anomaly, but appears to be indicative of a trait that is nearly fixed throughout the Calcasieu drainage. To date the genetic basis of iris color in *Graptemys* has not been studied.

There is only one previous report quantifying variation in eye color in species of *Graptemys*, for two syntopic species in the lower Tennessee River drainage in western Kentucky (Lindeman 2003). *Graptemys ouachitensis* was consistent in having a striped white iris, while most *G. pseudogeographica* had an unstriped white iris, with low incidence of black stripes (5%) or small black dots anterior or posterior to the pupil on the iris of one or both eyes (16%). Both species also had low incidence (<5%) of light-yellow coloration invading the white iris. Together with the present report and unpublished observations of other species by PVL, these results suggest that it is typical for *Graptemys* species to have fixed or nearly fixed conditions for iris color and markings at the levels of both local population and drainage-wide metapopulations.

In contrast to iris color and markings, chin patterns were highly variable within the Calcasieu drainage. Of 24 specimens examined or photographed while basking, nine had chin bars and three had intermediate, interrupted patterns more suggestive of a chin bar than of the three-spot pattern that is typical of *G. pseudogeographica* (Vogt 1993). The two adjacent drainages did not show variability, with none of 17 turtles captured or photographed while basking showing a chin bar. A chin bar has not been reported from any other population of *G. pseudogeographica*. Vogt (1993) did not report the condition among large samples of *G. pseudogeographica* collected from several localities throughout the species' range (not including the Calcasieu drainage). He did report that *G. ouachitensis* hatched under laboratory incubation conditions sometimes exhibited a chin bar instead of the three-spot pattern that is also characteristic of that species, but found no chin bars in wild-caught *G. ouachitensis*

specimens taken range-wide. There are also no reports in the literature of any of the 6 *Graptemys* species that are characterized by chin bars having any individuals exhibiting a three-spot pattern (Carr and Marchand 1942; Cagle 1952, 1953a, b, 1954; Haynes and McKown 1974; Lovich and McCoy 1992). However, Ennen et al. (2010b) reported lack of the chin bar (without details regarding alternate patterns) at low frequencies in *G. flavimaculata* and more commonly in *G. oculifera*; in addition, in *G. sabinensis*, an intermediate pattern of interrupted chin bars forming two or three separate markings—albeit not spots widely separated by several intervening light lines or whorls—sometimes occurs (PVL, unpubl. data). For a mix of *G. barbouri* (typically a chin bar), *G. ernsti* (typically a spot-line-spot pattern), and their hybrids in the Choctawhatchee drainage, Godwin et al. (2015) reported a mix of chin patterns but unfortunately did not report which animals had which pattern according to their genetic classification as one species or the other, or a hybrid.

Overall, chin patterns appear to be highly consistent species characteristics in *Graptemys*, except in the case of the Calcasieu drainage populations of *G. pseudogeographica*. As with iris color and patterning, the genetic basis of chin patterns is unknown and awaits further study.

The genus *Graptemys*, as currently recognized, has 14 species, nine of which are confined to single Gulf Coastal drainages, with three others distributed in 2–3 adjacent drainages (Lindeman 2013). Only *G. pseudogeographica* and *G. geographica* are distributed over more drainages (seven and five, respectively; Lindeman 2013). One group of drainage-endemic species was long considered conspecific, as *G. pulchra*, with a distribution spanning four adjacent drainages in eastern Louisiana, Mississippi, Alabama, Georgia, and the panhandle of Florida (Baur 1893; Cagle 1952). Detailed analysis of morphological variation resulted in the splitting of *G. pulchra* into three species, with one of them, *G. gibbonsi*, occurring in two adjacent rivers (Lovich and McCoy 1992), but subsequently a combination of morphological and molecular genetic analyses resulted in *G. gibbonsi* also being split into two species by drainage (Ennen et al. 2010a). The variable characters reported here appear to be indicators of unique variation in the Calcasieu drainage and further detailed morphological and molecular genetic analyses are warranted.

Irrespective of any possible taxonomic implications of the variation described herein, the unique dark eyes of Calcasieu-drainage *G. pseudogeographica* likely pose a conservation challenge. Species of *Graptemys* are highly regarded in the pet trade and collectors have recently become aware of "black-eyed" Mississippi map turtles, with both online and pet expo dealers offering them for sale (C. Lechowicz, pers. comm.). Trade in herpetofauna has been known to spike coincident with the discovery and description of new variants (e.g., Stuart et al. 2006; Phimmachak et al. 2012). Monitoring of both commerce and field collecting will be necessary to assess the threat that the pet trade poses to Calcasieu populations of *G. pseudogeographica*.

Acknowledgments—We thank C. Lechowicz for sharing his insights on trade in Calcasieu drainage *G. pseudogeographica*. Assistance in the field was provided by F. Armagost, K. Cantrelle, J. Eaker, A. Fehrenbach, and S. McFadden. Field work was supported by a Louisiana State Wildlife Grant.

Discovery of the Critically Endangered Finca Chiblac Salamander (*Bradytriton silus*) in Northern Chiapas, Mexico

Plethodontid salamander diversity and distributions in the Neotropics are active areas of research that are hindered by the increasing scarcity of species due to habitat destruction and disease (Rovito et al. 2009). Discoveries of species thought to be extinct, as well as of new localities for narrowly endemic species, provide new hope that these species will persist into the future. One of the most unique and enigmatic species of Neotropical salamanders is *Bradytriton silus*. Unlike any other species of Neotropical salamander, this species has a robust body, small feet, and a short snout. After its initial discovery in 1974 by Paul Elias at Finca Chiblac in the Sierra de los Cuchumatanes of Guatemala, *B. silus* was collected again in 1975 and 1977, but not thereafter (Wake and Elias 1983). The International Union for Conservation of Nature's (IUCN) Red List of Threatened Species list the species as Critically Endangered (CR) due to the destruction of natural habitat in and around the type locality, the lack of sightings, and the very limited range (Acevedo et al. 2008). *Bradytriton silus* thwarted researchers' efforts to rediscover the species until January 2009. Biologists from the Museum of Vertebrate Zoology, UC Berkeley and the Museo de Historio Natural, Universidad de San Carlos de Guatemala found nine individuals of *B. silus* while surveying Finca Ixcansán, near the small town of Yalambojoch, just under 29 km NW of Finca Chiblac (Papenfuss et al. 2010). This was the first sighting of the critically endangered species in 32 years. Another specimen was collected a year later near San José Maxbal, approximately 9 km NW of Finca Chiblac. These discoveries proved that *B. silus* was not yet extinct, and that it occurred outside of the type locality.

In June 2012, as part of an endeavor funded by the National Science Foundation to conduct biotic surveys of the vertebrate fauna in Nuclear Central America, a team of researchers from the Autonomous National University of Mexico (UNAM) and UC Berkeley visited a poorly explored region of northern Chiapas, Mexico. After trekking for two hours through secondary rain forest, the group reached the mountaintop village of San Francisco Jimbal, inhabited by only 62 individuals of indigenous Ch'ol heritage. The next morning, the herpetological faction of the survey team began searching for salamanders under cover objects and among vegetation. They found eight specimens of *Bradytriton* (Fig. 1) in leaf litter among the roots of a tree and under logs and boards in the forest. San Francisco Jimbal is 200 km NW of the type locality of *B. silus*, near the border of the Mexican states of Chiapas and Tabasco (Fig. 2). This collection is a new country record for Mexico and currently is the only record of *Bradytriton* outside of Guatemala.

Given the discovery of a population of *Bradytriton* so far outside its previously known range and the low likelihood that a salamander with such a stocky body and reduced limbs would have the ability to disperse across large distances, we examined mitochondrial sequence data to determine the level of genetic

TABLE 1. Locality information, voucher numbers, and GenBank accession numbers for samples used. Voucher numbers with asterisks were originally sequenced by the authors of this study.

Taxon	Locality	Voucher Number	16S	cytb
Bradytriton silus	Guatemala: Huehuetenango	MVZ 265366*	KP337339	KP337342
Bradytriton silus	México: Chiapas	MVZ 256828*	KP337340	KP337343
Bradytriton silus	México: Chiapas	MVZ 256829*	KP337341	KP337344
Bradytriton silus	Not recorded	MVZ 244269	DQ640058	DQ640023

divergence from other populations of *Bradytriton*. We sequenced both the 16S and cytochrome b genes using primers 16Sar/16Sbr and MVZ15/MVZ16 (Moritz et al. 1992; Palumbi 1996). Voucher numbers, locality information, and Genbank accession numbers for sequences used are summarized in Table 1. The Jukes-Cantor (JC) distance between Mexican *Bradytriton* and specimens from Finca Ixcansán, Guatemala based on an alignment of 16S and cytb is only 0.006, much lower than one would expect over a large geographic distance. Current knowledge of where *B. silus* occurs almost certainly does not represent the species' full range, but its discovery in Chiapas shows that the species is more widespread than previously thought. The IUCN's current classification of *B. silus* is partially based on its restricted range. If more extensive surveys of areas between the Sierra de los Cuchumatanes and the newly discovered locality in northern Chiapas show that *B. silus* occurs between these two points, its current CR classification by the IUCN may no longer be justified, especially considering that the species is thought to live in both natural and disturbed habitats (Acevedo et al. 2008).

Acknowledgments.—We thank David B. Wake and Theodore J. Papenfuss for feedback on this manuscript. Funding for field collection and lab work was provided by an NSF Biodiversity Survey and Inventory grant (DEB 1026396). Permits through SEMARNAT (Permit no. 10660) issued to Gabriela Parra-Olea allowed us to collect amphibians from the field.

Tracking Toads Using Photo Identification and Image-Recognition Software

Vital demographic information about animal populations in support of ecological research and endangered species management can best be gathered by tracking known individuals over time. In a great many animal species, patterns of spots, blotches, dots or stripes on the skin are sufficiently variable between individuals that they can be used for identification (Auger- Méthé and Whitehead 2006; Gilkinson et al. 2007; Chim and Tan 2012; Faber et al. 2013). For dealing with just a few individuals, all that may be required is a set of images or drawings that can be matched to the animals' markings by eye. Employing these patterns effectively for recognizing more than a small number of individuals over time, however, invariably requires photographs, a searchable archive for the photographs and an expeditious means of comparing the photographs to find matching patterns (Bolger et al. 2012). Larger numbers of individuals that have been photographed multiple times present a prohibitive difficulty for manual searching as it becomes exponentially more time-consuming and error-prone as the number of surveyed individuals increases. The method therefore requires digital photographs stored in a digital archive, searched by image-recognition software (Kelly 2001; Arzoumanian et al. 2005; Speed et al. 2007; Van Tienhoven et al. 2007; Martin-Smith 2011).

Though the value of software-based photo-recognition of animals is clear, and many attempts have been made to employ it (Speed et al. 2007; Van Tienhoven et al. 2007; Gamble et al. 2008; Auger-Méthé et al. 2011; Lahiri et al. 2011; Bolger et al. 2012; Petrovska-Delacrétaz et al. 2014), the challenge of building such software is not trivial. In order for software to be able to compare each new picture with every other picture stored in a database and so find every matching color pattern for every animal, it has to discern and store information about the animal's markings in the pictures, and it has to compensate for variation in the size, quality, pixel density, and orientation of the picture while it does so (Kelly 2001; Bolger et al. 2012). It also has to be reasonably easy to use and provide the user with the means to validate both input and output. A secondary requirement for the use of photo-recognition is that the animals' markings remain stable over time. Although this is usually the case, there are exceptions (Gowans and Whitehead 2001; Yoshizaki et al. 2009; Jonas et al. 2011; Waye 2013) and so mark stability should be examined case-by-case. Mindful of previous efforts to program and implement image-based visual recognition systems, we have designed a semi-automated software system, which we have named "Foto-Spottr," that has innovative attributes enabling efficient searching through a database of digital images to find likely matches to a given individual animal.

We used Fowler's Toads (*Anaxyrus fowleri*) as our focal species for the design of our system. These toads have unique patterns of irregular dark dorsal spots that can identify them like a fingerprint (Fig. 1). A trained researcher can readily recognize an individual toad from photographs, even when the images are taken years apart. A long-term mark-recapture study of this species at Long Point, Ontario, Canada (Smith and Green 2006; Greenberg and Green 2013; Green and Middleton 2013) had used toe-clipping to identify individuals but, in recent years, also took digital photographs to confirm individual identities in cases where the toe-clips were hard to read. Thus a large bank of digital photographs was readily available for our use in designing and testing our software system and for examining the stability of individual markings over time.

To be comparable, photographic images of the animals need to be standardized. That is, they need to show the same part of the animal at the same orientation to the camera and be of the same pixel density, brightness, and contrast. Some of this may be achieved as the photo is taken by holding the animal in a particular way against a particular background and maintaining the camera's settings, orientation, and distance from the subject for all pictures (Doody 1995). Though it is clearly advantageous to have as much consistency as possible among the pictures, maintaining an exact and fully repeatable picture-taking protocol in the field, especially using hand-held cameras, can be difficult and time-consuming. Computational post-processing to align the animals' identifying features among various photographs is unavoidable and we chose to emphasize this aspect of the process to simplify picture-taking in the field as much as possible.

Foto-Spottr is able to use pictures that were not necessarily taken for use in animal identification or were taken under difficult and variable field conditions. We use digital photographs taken in the field, at night, using a small, handheld waterproof camera (e.g., Pentax Optio or equivalent). The image density is

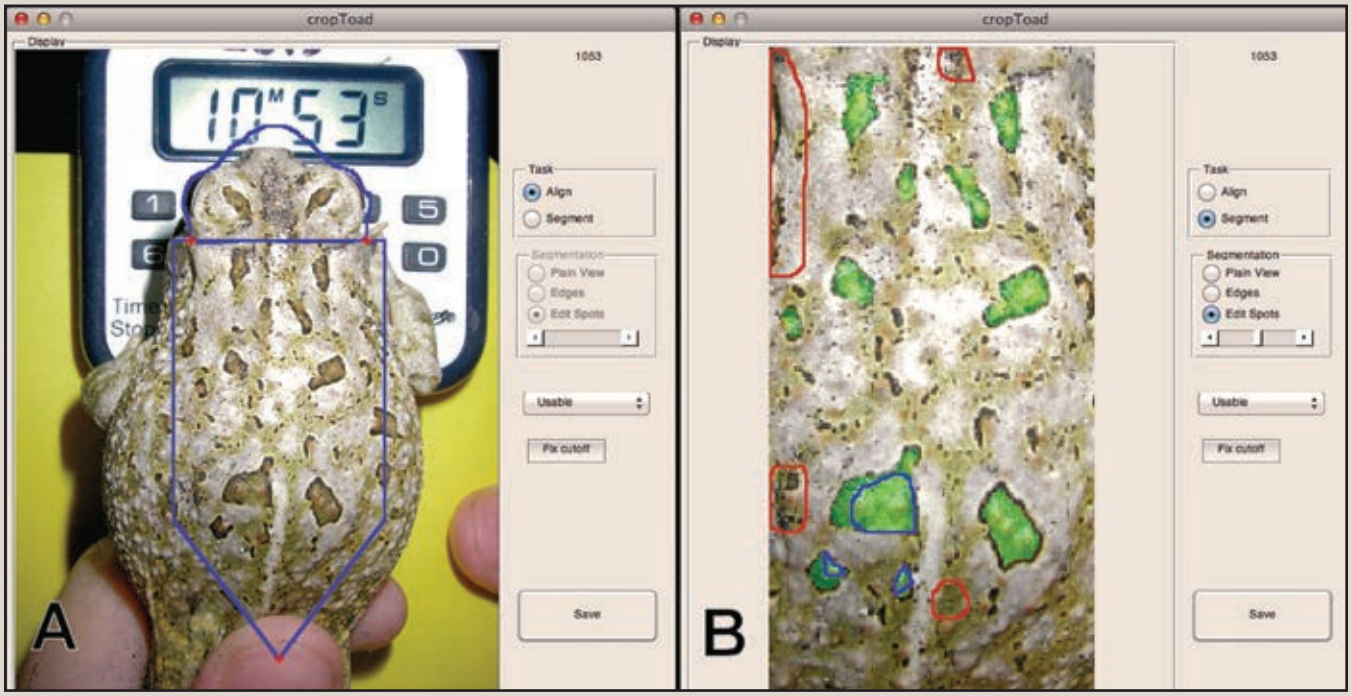

FIG. 1. Input window. A) Standard digital photo of the animal in question, in this case an adult female caught in 2013 and recorded as encounter No. 1053 for that year. The image has superimposed upon it the outline frame (blue) that specifies the region to be analyzed. The frame is placed by clicking on the image behind each eye and on the animal's posterior (red crosses). B) Editing window. Segmentation highlights all probable spots in green. This can be edited manually by outlining undetected spots (blue) or deleting incorrectly highlighted areas (red).

set to 2–4 megapixels/image. Larger images are neither necessary nor desirable as they slow down processing and occupy greater archive space. Each photograph shows the dorsal surface of a single toad against a plain background (Fig. 1A). A lab timer included in each picture serves both as a size standard and a device to record an image identifying number.

The animals in the images vary in size in three ways: the animal's actual body size, the pixel density of the image and the amount of the frame filled by the animal. Also, the animal is not necessary aligned consistently with respect to the frame. To compensate, the user of the software can call up the image into a processing environment and place a generalized animal shape on the image of the animal to roughly specify the region of interest. For toads, the animal's outline could be approximated with a triangle on the head and a pentagon on the body, anchoring the vertices at the posterior corners of the eyes (Fig. 1A). This process takes only a second and compensates for variations in image size and orientation. In the present version of Foto-Spottr, only the rectangular region of the animal's back is used for image matching.

Once the region of interest is specified, an automatic color segmentation routine (Cheng et al. 2001) finds most or all of the spots and highlights them in color (Fig 1B). The user then has the option to review the result and make corrections as necessary. Using the mouse, the user can outline additional spots for the computer, refine the shapes of spots or remove erroneously highlighted areas, generally due to sand or debris adhering to the animal's back or shadows resulting from the uneven surface of the animal. This step may not be necessary for high-quality photographs of animals with well-defined spots, or may take up to a minute or two to compensate for low-contrast photographs of animals with ill-defined spots. The computer then stores a two-color image of the highlighted spots within the specified region of interest, linked to the original image.

At this point, Foto-Spottr automatically searches for matching images by comparing the two-color spot pattern of the target image to that of every other similarly processed image in a database. The match-quality between two images is based on the number of overlapping pixels in the two-color patterns, but the images need to be well aligned before this is meaningful. The step of cutting out a rectangle from the back is sufficient to get the patterns into rough alignment but a more precise alignment is computed in software. Foto-Spottr uses Lucas-Kanade affine template tracking (Baker and Matthews 2004; Schreiber 2007) to compute an affine transform that maximizes the similarity between the two images. This algorithm is designed to track moving objects through subsequent frames of a video, but we found that it is also ideal for correcting the differences between still images taken at different times. The affine transform overcomes many routine misalignment problems between pairs of photos and allows the system to make direct comparisons of images, rather than of data derived from images as is done in various other systems (Auger-Méthé and Whitehead 2006; Speed et al. 2007; Lahiri et al. 2011; Petrovska-Delacrétaz et al. 2014). We used the public domain MATLAB function shared by Dirk-Jan Kroon (MATLAB Central <http://www.mathworks.com/matlabcentral/fileexchange/24677-lucas-kanade-affine-templatetracking>) to implement the robust Lucas-Kanade template tracking algorithm into our system. The final match-quality score is based on the number of overlapping pixels after the final alignment.

Once Foto-Spottr has completed its database search, it displays the ten best matches, based on % pixel overlap, alongside the target image so that the user can visually verify the match (Fig. 2). In the great majority of instances, the best match should be another image of the same individual taken at an earlier time. If not, and the animal has been caught before, then one of the

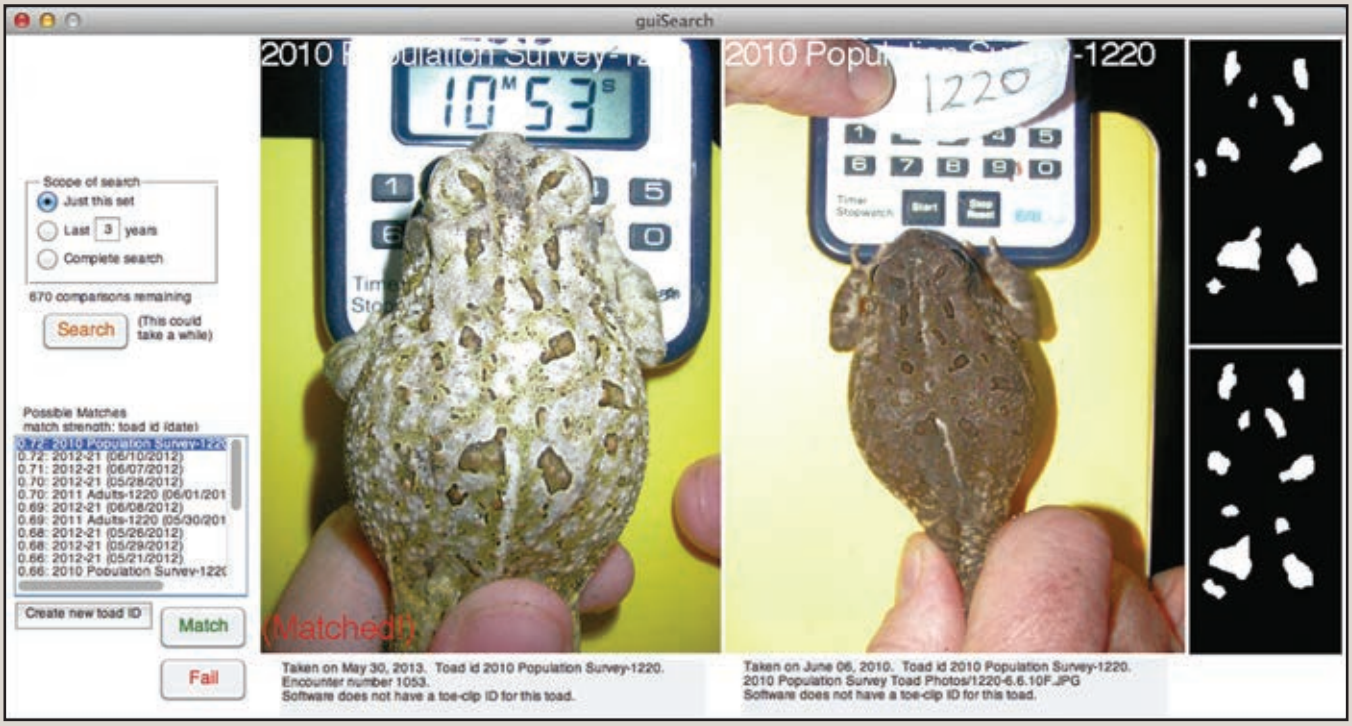

FIG. 2. Output window showing results of computer imaging searching for matches to the target (left image) image. The best match (right image) is clearly of the same toad caught when it was a juvenile three years previously in 2010 and assigned No. 1220. Despite differences in size, alignment and aspect in the two photos, the program found 72% alignment of the animal's spots in each image, as shown in the output window (lower left). To help confirm the match by eye, the aligned two-color spot patterns obtained from each image are displayed (far right).

next two to five best matching images will almost invariably be that individual. If there is no good match among the 10 closest matching images, it can be assumed that the animal is new and Foto-Spottr will indicate its failure to find a match.

Applied to a test set of 560 pictures of Fowler's Toads that had been taken in previous population surveys of toads (Smith and Green 2006), Foto-Spottr required about a minute of manipulation time per image but greatly decreased the number of comparisons that needed to be verified by eye. Applied to pictures of animals that had been identified with toe-clipping, our system placed the correct match among the top five possible matches 91% of the time. This was comparable to the accuracy of the best physical tagging techniques (Bolger et al. 2012). Even so, the pictures we used were not staged for software recognition; they were taken as a routine part of the field protocol of the time. We have since refined our field procedure to get better, more consistent pictures, and our success rate has increased. Foto-Spottr also found matches that were previously missed based on toe-clip identifications and was able to identify animals as they grew (Fig. 2), confirming the temporal and ontogenetic stability of the markings on these animals.

One new property of the process of identifying animals using an image-based system, compared to physically marking them, is that an animal's identity usually cannot be established at the time of capture. Images are therefore tagged with field-given "encounter" numbers and recorded as such in the field notebooks. These later have to be amended with the animal's actual identification number. Thus each encounter with any particular animal had to be recorded and numbered along with the animal's specific ID, and field notes have to be corrected after the fact. Foto-Spottr is designed to streamline this process of logging ancillary data associated with each image, such as existing toe-clip, PIT, VIE, or VI Alpha Tag IDs, biometric information, and the date and location of capture.

There are numerous differences between Foto-Spottr and other available computer-assisted photo-ID systems. Our system is currently implemented in MATLAB 8.0 (The MathWorks, Inc., Natick, Massachusetts, USA) to take advantage of shared functions such as Kroon's Lucas-Kanade algorithm. It is also pixel-based, with automatic recognition of shapes no matter how irregular in outline they may be, and uses position, size, and shape information in searching for matches. These aspects distinguish Foto-Spottr from I^{3}S software (Van Tienhoven et al. 2007) which matches the position of user-selected points on the animal or, in its latest versions, user-drawn ellipses around spots, and from WILD ID software (Bolger et al. 2012) which first uses a Scale Invariant Feature Transform (SIFT) operator to extract point information from images and then takes a "brute-force" approach to compare all such features between pairs of images using a geometric algorithm. Both Stripespotter (Lahiri et al. 2011), which uses a dynamic programming algorithm adapted from signal-processing methods, and Identifrog (Petrovska-Delacrétaz et al. 2014), which employs principal components analysis adapted from machine-learning methods, are also more computationally intensive than Foto-Spottr, and have stricter requirements for the images they can use. All these various systems approach much the same problems with success but we contend that our approach makes input easier and yields results more rapidly.

Our initial results indicate that Foto-Spottr is already as effective as any system currently available (Speed et al. 2007; Bolger et al. 2012). With optimization, its performance could be even further improved. The prototype of the software was initially installed on a Macbook Air (Apple Inc., Cupertino, California, USA)

laptop computer but we have now made a freely available version that can be readily installed in Windows™ systems. It is available for download at http://cnd.mcgill.ca/~aschoen/spottr/ or can be obtained directly from our code repository at https://github.com/toadmann/spottr. We expect to develop Foto-Spottr further as a stand-alone, open-source software system and user interface, which will allow it to be used in the field.

Software-based visual recognition that enables individuals to be identified without harming them makes the extensive use of toe-clipping and other invasive marking methods increasingly difficult to justify. Identifying individual wild animals has typically involved physically marking or tagging them and an assortment of methods has been applied to amphibians and reptiles (Donnelly et al. 1994; Ferner 2007). Such methods include tattooing (Perret and Joly 2002), freeze-branding (Lewke and Stroud 1974), toe-clipping (Waichman 1992; Reaser 1995; Lemckert 1996; Phillott et al. 2007) and injecting either passive integrated transponder (PIT) tags (Ott and Scott 1999; Blomquist et al. 2008; Hamed et al. 2008; Luhring 2009), visual implant elastomer (VIE) marks (Bailey 2004; Moosman and Moosman 2006; Grant 2008), or fluorescent Visible Implant Alphanumeric (VIA) tags (Buchan et al. 2005; Gower et al. 2006; Heard et al 2009) under the skin. Aside from ethical concerns related to these practices (Funk et al. 2005), there is potential for such invasive procedures to alter an animal's behavior, compromise its physical well-being, and threaten its survival (McCarthy and Parris 2004; Bloch and Irschick 2005; Liner et al. 2007). This is a particular concern for work with protected species. Not surprisingly, therefore, visual identification of individual animals based on their natural markings is an attractive alternative (Kurashina et al. 2003; Bradfield 2004; Del Lama et al. 2011; Sharifi et al. 2013), provided those markings are sufficiently discernable and distinctive (Kenyon et al. 2009). Increasingly improved software and hardware for photo-ID systems will represent significant advances in field methods that will be of direct benefit to ecological knowledge and the recovery of threatened species.

Acknowledgments.—We thank Flavia Papini, Jessica Middleton, Lauren Mechak, and Katharine Yagi for their recommendations and testing of the system. We also thank Phillipe Laroche for his help processing our archived images, as well as his input on the software design. Software development was supported by a grant from the Ontario Ministry of Natural Resources Species at Risk Research Fund to DMG.

Evaluation of Two Individual Identification Techniques for Spotted Salamanders (*Ambystoma maculatum*)

Introduction.—Mark-recapture (MR) is a widely-implemented and effective method used to monitor amphibian populations over time (MacNeil et al. 2011; Waye 2013). Long-term MR studies allow researchers to collect valuable information about the growth, movement, health, and dispersal of populations (Osbourn et al. 2011) that can ultimately be used to inform decisions regarding management and conservation of amphibians and their habitat.

Mark-recapture studies often require that each individual be identified as unique from others in the population. Common amphibian identification techniques include visible implant elastomer (VIE) tags (Bendik et al. 2013), visible implant alphanumeric (VIA) tags (Osbourn et al. 2011), toe-clipping (McCarthy and Parris 2004), passive integrated transponder (PIT) tags (Homan et al. 2008; Ousterhout and Semlitsch 2014), and pattern recognition (Loafman 1991; Foster et al. 2007). Each identification technique presents its own set of advantages and disadvantages, and therefore must be carefully considered before selecting a technique for long-term MR studies.

The scope and objectives of a study determine the most appropriate and feasible identification technique. The number of individuals that are likely to be captured, handling time per individual (i.e., amount of time necessary to identify each

individual), potential effects of the marking technique on behavior and health of the organism, longevity of the mark or tag, duration of study, and budget must all be considered (Osbourn et al. 2011). For example, although VIE tags are well-suited for marking very small animals, they offer a limited combination of codes. Even with six possible locations for tags on the body, four colors, and three tags per individual, only 1280 possible combinations exist (MacNeil et al. 2011), which may be insufficient for a multi-year study. VIE tags can also migrate beneath the skin or fragment after injection, making the code difficult to determine (Osbourn et al. 2011). Many techniques, including VIE tags, often require anaesthetization, constant monitoring of anaesthetized individuals, and the injection of a tag, which is time-consuming, invasive, and may have negative effects on behavior and stress levels (Kinkead et al. 2006; Osbourn et al. 2011).

As an identification technique, pattern recognition minimizes the need for invasive tagging methods by using natural color patterns as the primary identifier for each individual. The use of natural skin or fur patterns as markers has been successfully implemented with many different taxa, including polar bear whisker spot patterns, whale shark spot patterns, zebra stripe patterns, and bobcat spot patterns (Anderson et al. 2010; Arzoumanian et al. 2005; Foster et al. 2007; McClintock et al. 2013, respectively). Pattern recognition has also been evaluated before for use in MR studies of amphibians (e.g., *Ambystoma tigrinum*; Grant and Nanjappa 2006; Waye 2013). Assuming an individual's pattern does not change over time once they have reached the adult life stage, pattern recognition can be used for the entire adult life of each individual (Grant and Nanjappa 2006).

Some species of wetland-breeding salamanders (e.g., *Ambystoma* spp.) can serve as model amphibians for long-term MR studies using pattern recognition because of their individually distinctive patterning, relatively low vagility, and predictable movement patterns associated with reproduction (Petranka 1998; Semlitsch 2008). We developed an affordable and less-invasive MR technique for identifying individual Spotted Salamanders (*Ambystoma maculatum*) using spot pattern recognition. Our primary goal for this study was to assess the feasibility of using this pattern recognition (henceforth referred to as "spot code") as an alternative MR technique to VIE. Our assessment included measurement of identification accuracy and handling time for both techniques, where identification accuracy was defined by the percentage of correctly identified individuals by newly trained observers, and handling time was defined as the amount of time necessary to identify each individual.

Methods.— We conducted our study at a 0.93-ha ephemeral wetland located on a peninsula in Mountain Island Lake within Cowan's Ford Wildlife Refuge in Mecklenburg County, North Carolina, USA (35.3775°N, 80.9658°W). The wetland is surrounded by deciduous and pine forest and is dominated by tall grassy vegetation (Pittman et al. 2008). Each day we sampled 40 aquatic traps and 38 pairs of pitfall traps (13-L plastic buckets) placed every 10 m on either side of a 400-m drift fence completely encircling the wetland (Strickland et al. 2014). We sampled Spotted Salamanders from 18 January to 27 February 2014. A total of 253 individuals were processed and given spot codes in 2014. Individuals with VIE markings from previous years were identified as recaptures using the VIE code, but no new VIE codes were administered. Of the 253 individuals processed, 139 were recaptures with VIE codes and 114 were new captures.

The VIE marking technique was used in collection years prior to the current study. Salamanders were anaesthetized by submersion in Orajel® diluted to 1.0 g/L in 1L of water (Brown et al. 2004). A 26.5-gauge needle was then used to inject elastomer in any combination of six body locations (VIEs; Northwest Marine Technology, Inc., Shaw Island, Washington, USA). Salamanders could receive zero, one, or two colors in each location. The colors used were red, orange, yellow, and pink (Cecala et al. 2007; Fig. 1). An ultraviolet flashlight was used when reading the codes to increase visibility of the elastomer marks.

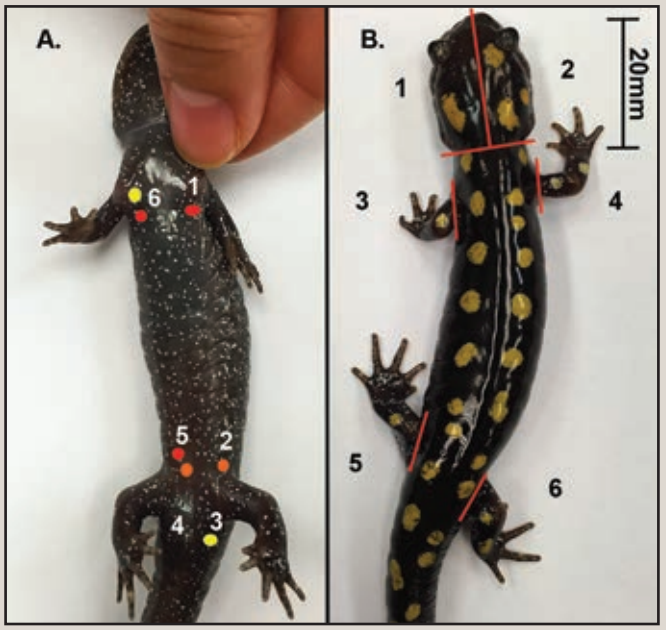

FIG. 1. Images of two Spotted Salamanders (*Ambystoma maculatum*) demonstrating two marking/identification techniques. A) Injection locations for the Visual Implant Elastomer (VIE) technique on the ventral side of a Spotted Salamander. This individual's code is 1R 2Or 3Y 5ROr 6RY—note that colored dots are not actual elastomer but only indicate locations and colors used. B) Demarcation of the six designated regions on the dorsal side of a Spotted Salamander developed for our spot pattern identification technique. This individual's spot code is: 131212. See Methods for a detailed explanation of both identification techniques.

We developed a spot pattern identification technique that relies on the number of spots in six designated regions on the dorsal side of each salamander. These regions are the left and right sides of the head anterior to the gular fold, and the four legs of the animal, from the feet (but not toes) to the top of the appendage where it joins the body (Fig. 1). Thus only head and limb spots, rather than spots on the trunk of the body, are considered in this technique. Orange and yellow spots ≥ 1 mm in diameter were counted in each of the six locations to create a spot pattern code. In order for a spot to be regarded as part of the official coding count, at least 50% of the spot's area must fall within one of the boundaries defined above. Irregularly shaped spots were counted as one spot unless a line of darker pigmentation passed through the spot. We recorded the spot code in a specific order: spot location 1 (left side of head), spot location 2 (right side of head), spot location 3 (left front leg), spot location 4 (right front leg), spot location 5 (left rear leg), spot location 6 (right rear leg). Thus, a salamander with two spots on each side of its head, one spot on each front leg, one spot on its left rear leg, and zero spots on its right rear leg was assigned the code 221110.

Of the 253 individuals processed in the 2014 season, 16 individuals had a shared spot code with at least one other individual,

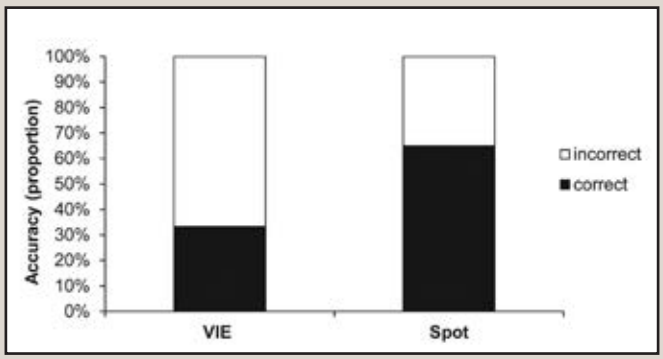

FIG. 2. Comparison of identification accuracy by identification technique. Proportion of trials correct and incorrect was derived from the total number of trials for each identification technique (N = 123 for VIE; N = 171 for Spot).

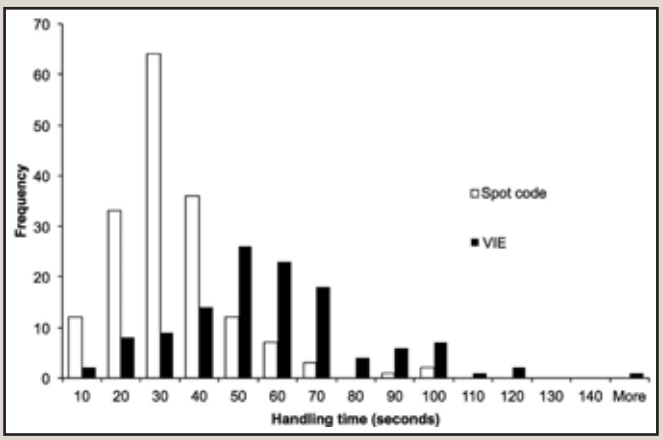

FIG. 3. Frequencies of time in seconds spent identifying individual salamanders (i.e., handling time) for each identification technique.

and one spot code was repeated four times. We accounted for these scenarios when two or more salamanders correctly receive the same spot code by adding a lower-case letter to the end of the spot code. Thus, the first individual captured with a given code would be 111111a, and a subsequent individual salamander with the same spot pattern would be 111111b. To help us differentiate between salamanders with the same spot code upon recapture, we took standardized photographs of the dorsum of each individual. Photographs were consistent with respect to background, angle, orientation, lighting, and distance from salamander. A ruler was also included in each photo to provide scale. These standardized photos were categorized in a computer database by spot code. Each individual spot code had its own folder in the database, and all photographs of a salamander with this spot code were stored in the folder for reference. Each photograph of a recaptured salamander was compared to database photographs to determine the identity of the individual captured. Photographs of each individual were also filed in the computer database under any alternate codes that might be mistakenly assigned to the salamander. Alternate codes were included when individuals had spots slightly smaller or larger than 1 mm or when spots lay on the boundaries of the designated regions, because these individuals are more likely to be misidentified. In the event of a misidentification, the identifier could find the salamander by looking up the mistaken code, but the image file would point them to the correct code.

To measure identification accuracy and overall handling time, we haphazardly selected salamanders that had been captured at our study site and brought back to the laboratory for processing. Processing individuals involved checking for a VIE code, reading the VIE code if it existed, assigning a spot identification code, taking a photograph of the dorsum, and taking the following measurements: mass (g), total length to the nearest mm (TL), and snout-to-vent length to the nearest mm (SVL). After processing, salamanders were haphazardly chosen to be used in our identification test (ID test) in which fifteen participants were asked to individually identify each salamander using both VIE and spot pattern techniques and record their results and handling time. Each identification of a salamander using one of the techniques was considered to be one trial. All participants had been trained in both techniques prior to ID testing, but participants were not informed of the correct VIE and spot codes for the salamanders they were identifying and were not permitted to crosscheck their identifications with the spot code or photo database. Finally, when participants identified an alternate spot code of a salamander, rather than the official code, this trial was still counted as a correct identification. Alternate codes are considered correct because when processing, identifiers would have access to the database where salamanders are cross-listed under both their official code and their alternate code(s).

We used program R (R Core Team 2013) to perform a mixed-effects logistic regression to determine whether identification technique was a significant predictor of identification accuracy. The binary response variable in this model was whether or not the salamander was identified correctly (yes or no) and the fixed predictor variable of interest was the identification type (VIE or spot code). We specified individual salamander as a random effect because individual salamanders were tested repeatedly. We also specified individual observer as a random effect because not all observers identified each salamander. The odds ratio for identification accuracy was used to determine the relative likelihood of correctly identifying individuals with each technique. We conducted a Student's t-test to determine if there was a difference in handling time (i.e., amount of time necessary to identify each individual) between VIE and spot code MR techniques. Alpha was 0.05 for all tests.

Results.—We conducted 171 trials for spot code and 123 trials for VIE on 41 *A. maculatum* individuals, totaling 294 trials. VIE trials matched the correct database codes 33% of the time, while 65% of spot code trials matched the correct database codes (Fig. 2).

We found that overall handling time using the spot code technique was significantly less than handling time using the VIE technique (Fig. 3; mean VIE = 54.2 ± 25.6 sec, mean spot code = 29.6 ± 14.9 sec; t-stat = 29.48; $p \leq 0.0001$). We found identification technique (e.g., VIE and spot code) to be a statistically significant predictor of identification accuracy (z-value = -5.092, $p \leq 0.0001$), with an odds ratio of 0.24 (95% CI 0.14–0.42). The odds ratio indicates that the participants were less likely to correctly identify a salamander when using the VIE technique than when using spot codes.

Discussion.— Our newly developed pattern recognition (spot code) technique for individually identifying Spotted Salamanders resulted in reduced handling time and improved accuracy compared to VIE techniques. Salamanders identified using the spot code technique took, on average, 25 fewer seconds than VIE and were twice as likely to be identified correctly than with VIE. Differences in standard error of handling time revealed our spot code technique to be more consistent than the VIE technique.

After six years of marking 2644 individuals from this *A. maculatum* population using VIE, we had exhausted many of the available code permutations. Our VIE marking technique yields a theoretical total of 6528 code permutations, but the more tags each salamander has, the longer its handling time, making the use of code combinations too time-consuming and expensive to be feasible for a daily trapping schedule. However, the theoretical maximum number of spot code permutations is limited only by the maximum number of spots in each body region. Of the 253 individual salamanders processed and assigned spot codes in the 2014 season, the maximum number of spots observed on any head region was seven, and the maximum number of spots observed on any appendage was five. If we assume these numbers to be the maximum number of spots possible in each location, then spot code yields a theoretical total of 82,944 possible permutations.

Furthermore, we found that the spot code technique is relatively easy to learn. Newly trained laboratory members had little difficulty with spot pattern but struggled through the duration of the study to correctly identify salamanders using VIE. One issue was that VIE colors (e.g., red and pink) were often difficult to discern. Migration and fragmentation of elastomer marks occurred as early as one year after VIE injection, causing some marks to be overlooked and others to move to ambiguous locations outside of the marking areas. With these difficulties, only experienced lab members with access to the full *A. maculatum* database could successfully identify VIE codes on a consistent basis.

Because the spot code identification technique was shown to have a shorter and more predictable overall handling time than the VIE identification technique, it is easier to predict how long processing will take. Low identification accuracy of our technique (65% accuracy) was an unexpected result. Other studies of VIE report identification accuracies of 87%, 83%, 81%, and 69% (Osbourn 2011). Other studies of manual pattern recognition report identification accuracies of 96.5%, 96%, or 97% (Loafman 1991; Grant and Nanjappa 2006). However, our observers were newly trained and thus had little experience in identification. We believe that as participants become more experienced with identification in future sampling seasons, the level of identification accuracy and standard error of handling time will improve rapidly. Further, we predict that ability of participants to crosscheck their observations through access to the database and standardized photographs would greatly improve identification accuracy.

Unlike other commonly used mark-recapture techniques such as toe-clipping, VIE, VIA, or PIT tagging, spot pattern is noninvasive and requires no use of anesthesia. Implementation of our technique is feasible, especially when standardized photos are taken of the dorsal side of each animal and additional alternate codes are given to animals whose spot code represents a borderline case (e.g., spot close to the 1-mm cutoff mark). These standardized photos are categorized in a computer database by spot code, so comparison of photographs to recaptured salamanders is straightforward when confirming salamander identity. The spot code technique is applicable to large populations and provides an easy and more effective way to identify individuals.

One concern with using spot pattern as a mark-recapture technique is that an individual's spot pattern could change over time, rendering spot pattern ineffective as an identification technique. Jonas et al. (2011) emphasize the importance of knowing whether or not body markings are variable before relying on these markings to identify individuals in a study. There are no published studies evaluating ontogenetic change in spot pattern in *A. maculatum,* although such studies do exist for other species: both *A. tigrinum* and *Eurycea longicauda longicauda* exhibit variation in spot pattern and coloration over time (Jonas et al. 2011; Waye 2013). As we accumulate images of recaptured individuals in future years, we can ensure whether or not spot patterns remain consistent over time by comparing images of salamanders identifiable by preexisting VIE tags and noting any changes.

We recommend further investigation into computer-assisted pattern recognition technology for Spotted Salamanders. Many studies have demonstrated the success and effective use of computer software in assigning identities based on unique natural patterns (Arzoumanian et al. 2005; Foster et al. 2007; Gamble et al. 2008; Anderson et al. 2010; Bendik et al. 2013; McClintock et al. 2013), but no software has been developed for this ambystomatid species. This technology could be applied to the standardized photographs taken of each salamander. Development of software to analyze spot pattern and assign individual identities to salamanders would reduce the issue of repeat codes and alternate codes and therefore has the potential to reduce human error in the identification process. A suggested approach would be to emulate the algorithm employed by Gamble et al. (2008) with *Ambystoma opacum*, which compared images based on visual similarity rather than on discrete geometric features. Software systems that extract shapes or distinct patterns and then apply a matching algorithm can struggle to identify large, irregular shapes like the spots of *A. maculatum*, so this visual comparison approach is more likely to yield successful results (Anderson et al. 2010).

Acknowledgments.—We thank members of the Davidson College Herpetology Laboratory, and in particular Kristen Cecala and Jacquelyn Guzy, for assistance in construction of the drift fence and data collection. We thank Michael Osbourn and Justin Strickland for comments that improved this manuscript. We also thank Mecklenburg County Department of Natural Resources, especially Don Seriff, Gary Marshall, Lenny Lampel, and Chris Matthews for site access and logistical support. Funding was provided by Davidson College Department of Biology. All work was carried out in accordance with Davidson College IACUC and a permit from the North Carolina Wildlife Resources Commission.

Evaluation of Gastric Lavage Method for Diet Analysis of the Eastern Red-backed Salamander (*Plethodon cinereus*)

Given global declines in amphibian populations, it is important to understand their roles as predators and how changes in their abundance (or local extinctions) may result in trophic cascades within a food web. Terrestrial salamanders are abundant, generalist predators and play a significant ecological role in forest food webs (Burton and Likens 1975a; Davic and Welsh 2004). Plethodontid salamanders act as top-down regulators of the soil invertebrate community and are a food source to higher order consumers (i.e., small mammals, birds, other amphibians), providing a link between below and above-ground food webs (Burton and Likens 1975a; Davic and Welsh 2004; Walton 2006; Walton 2013). Analysis of plethodontid diets allows insights on their top-down effects on soil faunal communities, and in turn, how these effects may indirectly influence ecosystem processes such as decomposition and nutrient cycling (Walton 2013; Best and Welsh 2014). Non-lethal methods to collect diet samples are preferred to sacrificing individuals to lessen the impacts of research activities on salamander populations, especially for rare and threatened species.

Stomach flushing (i.e., gastric lavage) is a non-lethal technique that has been used successfully to collect stomach samples from crocodilians, lizards, chelonians, anurans (Legler 1977; Legler and Sullivan 1979; Fitzgerald 1989; Rice and Taylor 1993; Solé et al. 2005), and caudates (Cecala et al. 2007; Sebastiano et al. 2012). The advantage of gastric lavage is that it does not require animals to be euthanized, so individuals may be resampled and populations monitored over time without impacting local abundances (Crovetto et al. 2012). The method involves gently pushing water into the stomach via a soft tube inserted in the esophagus, which forces the animal to regurgitate its stomach contents. If the procedure is done immediately after foraging the ingested material is still sufficiently intact for identification and estimation of prey volume.

The Eastern Red-backed Salamander (*Plethodon cinereus*) is a highly abundant terrestrial salamander in hardwood forests

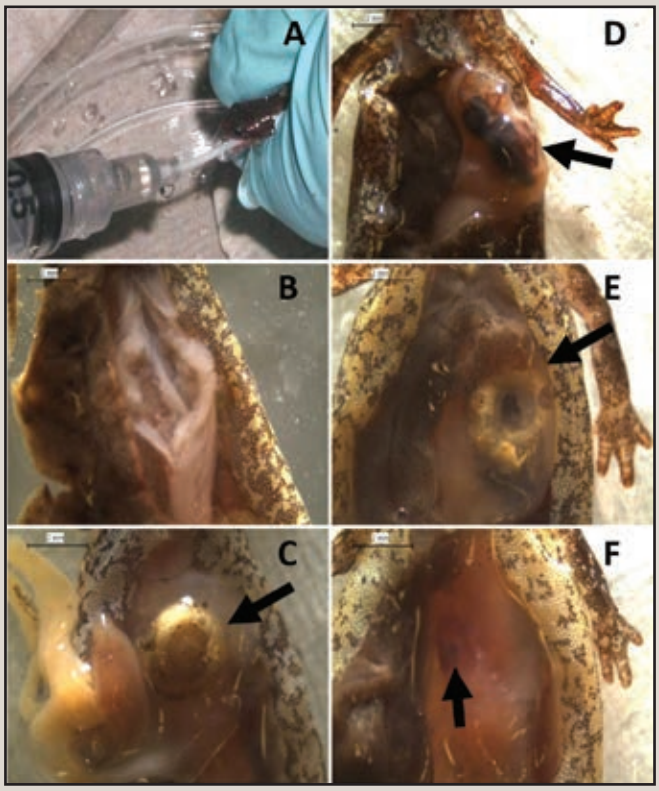

FIG. 1. Stomach flushing procedure on adult *Plethodon cinereus* using catheter tube and distilled water (A; photo by C. Snyder), successful lavage that has completely emptied all stomach contents and with no signs of tissue damage; (B) lavage that did not fully empty the contents of the stomach (C and D), salamander that did not regurgitate stomach contents following lavage but had a full stomach (E), damage to stomach tissue of a salamander that was lavaged and regurgitated all of its stomach contents (F). Scale bar represents 2 mm in plates B–F.

TABLE 1. Summary of 124 dissected *Plethodon cinereus* that had their stomachs flushed before being euthanized. Salamanders are categorized by whether they regurgitated stomach contents due to gastric lavage and if the dissected stomach was completely empty.

Lavage induced regurgitation of diet sample	Stomach empty: Yes	Stomach empty: No	Total
Yes	93 (75%)	12 (10%)	105 (85%)
No	13 (10%)	6 (5%)	19 (15%)
Total	106 (85%)	18 (15%)	124 (100%)

(Burton and Likens 1975b) with a range that extends from North Carolina north to include the Canadian Maritime provinces and southern Quebec, and west to northeastern Minnesota. As a dominant vertebrate predator, *P. cinereus* is the focus of many studies on salamander behavior, resource selection, and trophic interactions in forest food webs. A generalist predator, their diet is composed of microinvertebrates (i.e., Acari and Collembola), and other small invertebrates: arthropod larvae (Coleoptera and Diptera), Hymenoptera, Coleoptera, and Gastropoda (Burton 1976; Fraser 1976; Maglia 1996; Snyder 2011). Gastric lavage has been used extensively to study diet in *P. cinereus* (Fraser 1976; Maglia 1996; Maerz et al. 2005; Anthony et al 2008; Homyack et al. 2010; Ivanov et al 2011; Snyder 2011). However, in only one of these studies was any attempt made to assess the efficacy of the method; and only 10 salamanders were dissected to evaluate the proportion of prey left behind post stomach flushing (Maglia 1996). In another study, Diaz (2010) found gastric lavage ineffective for removing stomach contents for *Eurycea nana*—an aquatic plethodontid. Moreover, it is unknown whether certain prey types have detection bias using the lavage technique. A quantitative assessment of success rate and biases associated with certain prey items is needed to assess uncertainty in plethodontid diet samples collected by stomach flushing.

As part of a larger research project investigating trophic interactions of *P. cinereus* in northern hardwood forest food webs, we collected diet samples from 124 salamanders using gastric lavage and compared these samples to dissected stomach contents. Our objectives were to 1) evaluate the efficacy of gastric lavage at removing the stomach contents of *P. cinereus*, 2) determine which, if any, prey items are less detectable by gastric lavage (which may bias the diet sample), and 3) describe the condition of prey items obtained by stomach flushing.

Stomach flushing and salamander collection.—We conducted surveys for *P. cinereus* at nine northern hardwood sites located in the Green and White Mountains of Vermont and New Hampshire. Surveys were done between 24 June and 6 July 2012 and began at 0515 h each morning. Surveys involved three people searching the forest floor, and under cover objects (e.g. woody debris, bark, fern mats), for 30 minutes. All salamanders captured were placed in plastic bags until processing, but were not held in bags longer than two hours. Each salamander was weighed to the nearest 0.05 g, and total length (TL), snout-to-vent (anterior angle; SVL), and maximum head width (HW) were measured to the nearest 0.1 mm with digital calipers.

Stomach contents were collected from individuals greater than 28 mm SVL using gastric lavage (Fraser 1976). Salamanders were immobilized by wrapping them in a moist paper towel; this also maintained the body in a linear orientation to keep the esophagus straight. The salamander was oriented vertically head-down over a glass dish and the mouth gently opened with forceps. To flush the stomach, a soft plastic catheter, with an outside diameter of 1.0 mm and attached to a 30-cc syringe, was inserted into the esophagus and down into the stomach. Distilled water was gently pushed into the stomach until the salamander regurgitated its stomach contents, which came out in a single bolus (Fig. 1), often immediately following the introduction of water. Any material caught in the salamander's mouth was removed with forceps. All stomach contents were stored in 70% ethanol for identification. If no stomach contents were produced, a second flushing was conducted. For each salamander, we recorded either that the lavage resulted in regurgitation of stomach contents, or that no stomach contents were regurgitated. The same field technician performed stomach flushing on all salamanders and the entire procedure took 3–5 minutes per individual. Salamanders were then euthanized in the field using an application of 20% Benzocaine on the ventral surface of the salamander's body (Chen and Combs 1994). Salamanders were stored on ice during transportation to the lab, where specimens were stored in a -20°C freezer.

Salamanders were dissected using a digital stereomicroscope (Leica Microsystems, Buffalo Grove, Illinois, USA) to assess their stomach contents. All stomach contents were removed and photographed, we identified prey items to the lowest taxonomic

TABLE 2. Morphometric data for 111 *Plethodon cinereus* that were dissected post-gastric lavage and categorized by outcome, excluding those individuals that did not regurgitate contents because the stomach was actually empty (N = 13). Means and standard deviations are reported for SVL (snout-to-vent length), TL (total length), HW (maximum head width), and body mass (M).

Lavage Outcome	N	SVL	TL	HW	M
Removed all	93	37.4 ± 4.5	69.6 ± 10.1	5.5 ± 0.5	0.75 ± 0.3
Removed some	12	37.1 ± 3.3	69.2 ± 7.86	5.4 ± 0.6	0.70 ± 0.2
Removed none	6	36.4 ± 3.2	69.7 ± 9.2	5.5 ± 0.3	0.73 ± 0.2

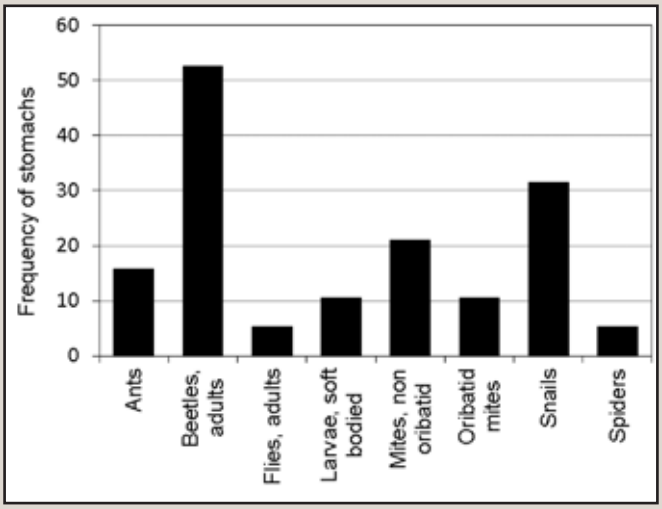

FIG. 2. Frequency of dissected stomachs with prey groups post-lavage (N = 18).

resolution possible (usually order or family), and measured the length and width to the nearest 0.01 mm. We calculated the percent of dissected salamanders that had either: 1) a completely empty stomach, 2) some prey items remaining in stomach, and 3) a full stomach. These data were used to evaluate the efficacy of gastric lavage. To determine whether salamander body size had an effect on efficacy, we used a one-way ANOVA to compare mean SVL, TL, HW, and body mass across outcome groups (i.e., empty, partial, full stomach). We also calculated the frequency of stomachs that contained each prey group to determine whether certain prey types were more commonly missed in stomach flushing samples (detection error).

Results.—Of 124 salamanders that were lavaged and subsequently dissected, 105 individuals regurgitated stomach contents and 19 did not regurgitate anything (Table 1). Ninety-three (75%) salamanders that regurgitated stomach contents were confirmed to have completely empty stomachs (Fig. 1; Table 1). Gastric lavage partially emptied the stomach of 12 (10%) salamanders, although in 7 of these cases only a single prey item was missed. Of the 19 salamanders that did not regurgitate anything after gastric lavage, 13 (10%) were confirmed to have empty stomachs and the remaining 6 (5%) had full stomachs (Table 1). If we exclude the 13 salamanders that did not regurgitate anything because their stomachs were truly empty, than flushing removed all of the stomach contents 84% of the time (93 out of 111), missed some prey items but removed most of the contents 11% of the time, and missed all of the stomach contents for 5% of the salamanders (Table 2). Overall, gastric lavage produced a diet sample 95% of the time.

There were no morphometric differences among salamanders that regurgitated none, some, or all of their stomach contents via gastric lavage (Table 2). The SVL ($F_{2,108} = 0.18$, $P = 0.84$), TL ($F_{2,108} = 0.01$, $P = 0.99$), and HW ($F_{2,108} = 0.06$, $P = 0.94$) were not statistically significant across the outcome groups (Table 2). There was also no difference in salamander body mass across the outcome groups ($F_{2,108} = 0.24$, $P = 0.78$).

We identified 45 prey items from the 18 lavaged salamanders that had remaining stomach contents after flushing. The most frequently missed prey groups were adult Coleoptera and terrestrial snails, which are both large, hard bodied prey (Fig. 2). Adult Coleoptera were present in 56% (10), and snails in 33% (6), of the 18 flushed stomachs that had remaining prey. Adult Diptera and arachnids had the lowest percent occurrence in the stomachs (Fig. 2). We were unable to calculate the prey volume missed because most of the stomach contents collected upon dissection were partially digested. In contrast, the condition of diet samples collected by gastric lavage were intact enough to positively identify invertebrates to functional group (Order) and obtain size and volume estimates.

Discussion.—We found that stomach flushing is an effective, non-lethal method to collect diet samples from *P. cinereus*, removing all or most of the stomach contents 95% of the time. In cases where gastric lavage did not fully empty the stomach, often (58%) only a single prey item was missed. The prey most frequently left behind were adult Coleoptera and Gastropoda (i.e., land snails). Because these are larger-bodied prey, their omission would lower estimates of total prey volume consumed by a salamander.

The majority of salamanders that did not regurgitate anything after stomach flushing did have an empty stomach, but researchers should be mindful that some individuals might have prey in their stomach—which occurred for 30% of the salamanders that did not regurgitate anything. We repeated the procedure if a stomach sample was not produced the first time, but we did not make a third attempt, in order to minimize handling time of the animal. We used a 1-mm plastic catheter tube for stomach flushing; perhaps a thinner plastic catheter would increase lavage success by reducing obstruction of regurgitated material moving through the esophagus by the tube.

Stomach flushing produced diet samples that were in good condition for further identification and measurements. Plethodontid salamanders are nocturnal foragers, so diet samples are best collected in the early morning before stomach contents are digested. We conducted our surveys at dawn and flushed salamander stomachs within 2 h of capture. These stomach samples remained in good condition and we were able to measure the length and width of soft-bodied prey, such as dipteran larvae.

Gastric lavage is an effective and minimally invasive procedure. We observed damage to the stomach mucosa in only 3 of the 124 lavaged salamanders, possibly a result of the plastic tube entering the stomach (Fig. 1). We did not observe salamanders in captivity post stomach flushing, so we do not know whether the procedure changed their behavior or health. Previous research has shown anurans held in captivity after stomach flushing

accepted food within 2 h and were still healthy after one month of observation (Solé et al. 2005), and recaptured ranids that were previously flushed had prey in their stomachs (Rice and Taylor 1993). Recapture rates of stomach-flushed larval *Pseudotriton ruber* did not differ from those that were not flushed, indicating this method had no effect on survival rates (Cecala et al. 2007).

In conclusion, gastric lavage is an effective research technique for studying plethodontid diets without removing individuals from a population. This procedure can be easily performed in the field and animals immediately released in their environment, minimizing negative impacts on a salamander's behavior. Gastric lavage has an advantage over euthanasia when working in remote locations by reducing the materials carried to the study site, as the researcher only needs small vials and ethanol to store stomach samples, compared with transporting a cooler or fixative to store euthanized salamanders. We recommend performing gastric lavage in the early morning, after salamanders have finished foraging and retreated to their cover objects, to ensure stomach contents have not been digested and are in good condition for further analyses.

Acknowledgments.—Funding support for this project was provided by the USDA Forest Service Northeastern States Research Cooperative (www.nsrcforest.org). We are grateful to C. Snyder, C. Geyer, J. Whals, and A. Temple for their assistance with field and laboratory work, and to P. Ducey for providing input on an earlier version of the manuscript. This research was conducted in compliance with approved animal care guidelines provided by the SUNY College of Environmental Science and Forestry (SUNY-ESF) Institutional Animal Care and Use Committee (#120403). We obtained Scientific Collecting Permits to perform gastric lavage and collect salamanders from New Hampshire Fish and Game and the Vermont Fish and Wildlife Department (#SR-2012-12). We received approval to conduct our research in White Mountain and Green Mountain National Forests.

Ranavirus in Three Species of Amphibian and Unisexual *Ambystoma* in Ohio

Amphibian declines resulting from disease caused by chytrid fungus (*Batrachochytrium dendrobatidis; Bd*) and ranavirus have been widely reported (Daszak et al. 2003; Muths et al. 2003). Despite increased reports of disease events there remains a need for increased surveillance efforts (Gahl and Calhoun 2008). Disease surveys are important in discerning spatial patterns of infection, establishing distributional data, and determining geographic spread. Data from these surveys provide important baseline information upon which broader ecological investigations of disease dynamics can be based. We report the findings of a disease survey that documents the first published account of ranavirus in three amphibian species and in unisexual *Ambystoma* salamanders at ponds in northeast Ohio.

In July of 2011, 74 larval amphibians of seven taxa were collected from 11 ponds in northeast Ohio and tested for ranavirus infection. Ponds were located on three museum preserves: four ponds were located on the Mentor Marsh State Nature Preserve (MM) in Lake County while six ponds were located on the Grand River Terraces Preserve (GRT). Additional specimens were collected from Geneva Swamp (GS) in Ashtabula County. The MM is ~48 km NW of the GRT and ~51 km W of the GS. Geneva Swamp is ~11 km N of the GRT. Ponds were selected based on observed declines in egg counts and in larval survival. Larval *Ambystoma jeffersonianum, A. maculatum, A. texanum,* unisexual *Ambystoma, Hyla versicolor, Lithobates clamitans,* and *L. sylvaticus* were randomly collected in breeding ponds using dip-nets from 5–26 July. Because ponds in this study have been the subject of long-term monitoring the amphibian species assemblage is known. No time constraint was placed on search effort because the primary goal was acquisition of specimens for ranavirus testing. Search effort consisted of a team of four conducting an average of ten dips per person per pond. Since ponds were relatively small, effort was considered adequate for acquiring the prescribed number of specimens. Searches were concluded in a pond when either five specimens were collected of each studied species or when no other individuals of a taxon were found.

Genetic testing performed prior to this study confirmed the presence of hybrid individuals at study ponds, both *A. jeffersonianum* and unisexuals are present at GRT whereas *A. texanum* and unisexuals are present at MM and GS. Identification of larval unisexuals without genetic testing is impracticable, therefore the results include unisexual specimens.

Larvae were euthanized by immersion in 3% ethyl alcohol solution. Internal organs were swabbed to detect systemic infection as opposed to dermal swabs for surface exposure to ranavirus. Swabs were analyzed by Research Associates Laboratories, Dallas, Texas, and ranavirus was confirmed using a SYBR green-based Real-time PCR assay. Primers are the property of Research Associates Laboratories (personal communication 2014). Sterile nitrile gloves were used with each new specimen while scalpel blades and work surfaces were disinfected with a 20% bleach solution between uses. All equipment and boots were disinfected with a 10% bleach solution after each pond to prevent disease transmission (Phillott et al. 2010). All specimens were deposited in the herpetological collection of the vertebrate zoology department of the Cleveland Museum of Natural History. Estimates of disease prevalence were calculated for samples using Wilson Score method with continuity correction for 95% confidence intervals (Newcombe 1998).

Ranavirus infection was detected in 25 (34%) of the 74 animals tested, all of which were from four of six ponds in the GRT (Table 1). Thirty-eight percent of salamanders (*Ambystoma jeffersonianum*/unisexual and *A. maculatum)* and 25% of frogs (*Lithobates sylvaticus*) were infected with ranavirus. Sixteen (64%) of the 25 infected individuals exhibited symptoms of illness (lethargy; petechiation on the ventral surfaces particularly around the hind legs, vent, and mouth; swelling in the gular region; loss of righting response; and absence of predator avoidance) or were moribund, whereas the remaining nine animals showed no symptoms despite infection. Few *L. clamitans* individuals were found over all sites despite being typically abundant in both larval and adult forms. *H. versicolor* was also less abundant and occurred in lower frequency, however, this species only inhabits two ponds in this survey.

Amphibian declines at GRT were first noted in the 1990s, however, reproductive effort at ponds appeared to increase following restoration work in 1994 (TOM, pers. obs.). Routine monitoring of ponds showed a recapitulation of population declines in 2002, although no disease or mass mortalities events were observed. In July 2005 a complete die-off was observed at one pond, and

sick and moribund individuals were found in five other ponds. Larvae of three salamander taxa and one frog (*A. jeffersonianum*, *A. maculatum*, unisexual *Ambystoma*, and *L. sylvaticus*) exhibited red leg syndrome, the symptoms of which are similar to those of ranavirus. Diagnostic testing of larvae at these ponds showed the presence of red leg syndrome (*Pseudomonas*) in 2006 and *Bd* in 2007 (unpubl. data) but samples were not screened for ranavirus. Results from the current study show ranavirus infecting nearly half of animals tested on this preserve. The presence of these pathogens in GRT ponds may explain the decline of common species, like *L. clamitans*, as well as declines in oviposition and larval survival.

We cannot conclude that ranavirus is responsible for die-offs (and population declines) on this preserve partly due to the detection of other disease agents in previous and subsequent years. Additionally, further study will be needed to determine prevalence of disease, whether these are secondary or opportunistic infections, and to ascertain the extent of their contribution to declines. Moreover, it will be necessary to assess the contribution of environmental factors (e.g., water chemistry, water temperature, crowding, etc.) in driving disease events.

New Records of the Chytrid Fungus *Batrachochytrium dendrobatidis* in Honduran Frogs

The amphibian chytrid fungus *Batrachochytrium dendrobatidis* (*Bd*) has been implicated as a cause of amphibian declines in Honduras (Wilson and McCranie 2004a, b). However, knowledge about the pathogen's presence within the country is poor, and up to now, it is known only in seven frog species from two localities (Puschendorf et al. 2006; Kolby and Padgett-Flohr 2009; Kolby et al. 2010; Kolby 2011). Both areas, the Pico Bonito National Park and Cusuco National Park, are situated in northern Honduras (Fig. 1). More sampling effort is important to understand the occurrence of *Bd* in Honduran amphibians.

As part of a separate study in which we were collecting museum specimens, we also sampled amphibians for the presence of *Bd* at 23 localities throughout Honduras (Fig. 1) during rainy seasons in 2006, 2008, 2009, and 2010. We sampled 23 frog (N = 107 individuals), three salamander (N = 6 indiv.), and one caecilian species (N = 1 indiv.). Five of the frog specimens (2 *Craugastor lauraster*, *C. noblei*, *Lithobates vaillanti*, and *Pristimantis ridens*) and three of the salamander specimens (*Bolitoglossa longissimi*) sampled were juveniles, all others were adults. Two of the adult frogs sampled were found dead near a stream (*Craugastor laevissimus*; No. 18, Quebrada de Agua, Table 1). All other amphibians were captured by hand and euthanized using Chlorobutanol. A piece of skin (ca. 7–10 x 7–10 mm; depending on the size of the animal) was cut from the abdominal section from each frog and salamander specimen and the caecilian skin was taken from an abdominal section about one-third distance to the tail tip. Skin samples were fixed and stored in 95% high-grade ethanol for later PCR analyses. To minimize cross-contamination between specimens, each individual was kept in a new plastic bag until examination. We also wore surgical gloves that were changed between specimens. Instruments used to take samples were disinfected with high-graded ethanol (flame treated). To prevent the spread of chytrid between the separate field sites, used gloves and plastic bags were burned in a camp fire before leaving a site. There was no or a very small risk of spreading *Bd* zoospores between sample sites, because of the time between each sampling and the distances between the sites (see Fig. 1, Table 1).

DNA was extracted with DNeasy Blood & Tissue Kits (Qiagen) according to the manufacturer's protocol. Finally the DNA was eluted in 50 µl of buffer AE (Qiagen). Extracted DNA was preserved in Eppendorf microcentrifuge tubes containing 98% ethanol. DNA of *Bd* was detected with a modified quantitative real-time (qRT) TaqMan PCR assay according to the protocol of Boyle et al. (2004). In this assay the TaqMan probe was not conjugated with a minor groove binder, but included locked nucleic acid (LNA, N+) bases to elevate the melting temperature (5'-6FAM-CGA GTC+ G+AA+ C+A+A+ AAT-BBQ-3'). All qRT-PCR reactions were performed in a final volume of 20 µl on a LightCycler 480 (Roche Applied Science). The reaction mixtures contained 0.25 µM of each primer (ITS1-3 Chytr and 5.8S Chytr; Boyle et al. 2004), 62.5 µM of each dNTP, 1.5 mM $MgCl_2$, 6% BSA, 2 µl of 10× reaction buffer (BD, Solis BioDyne), 1 unit Taq DNA polymerase (AmpliTaq, ABI) and 1 µl DNA. Cycling profile consisted of

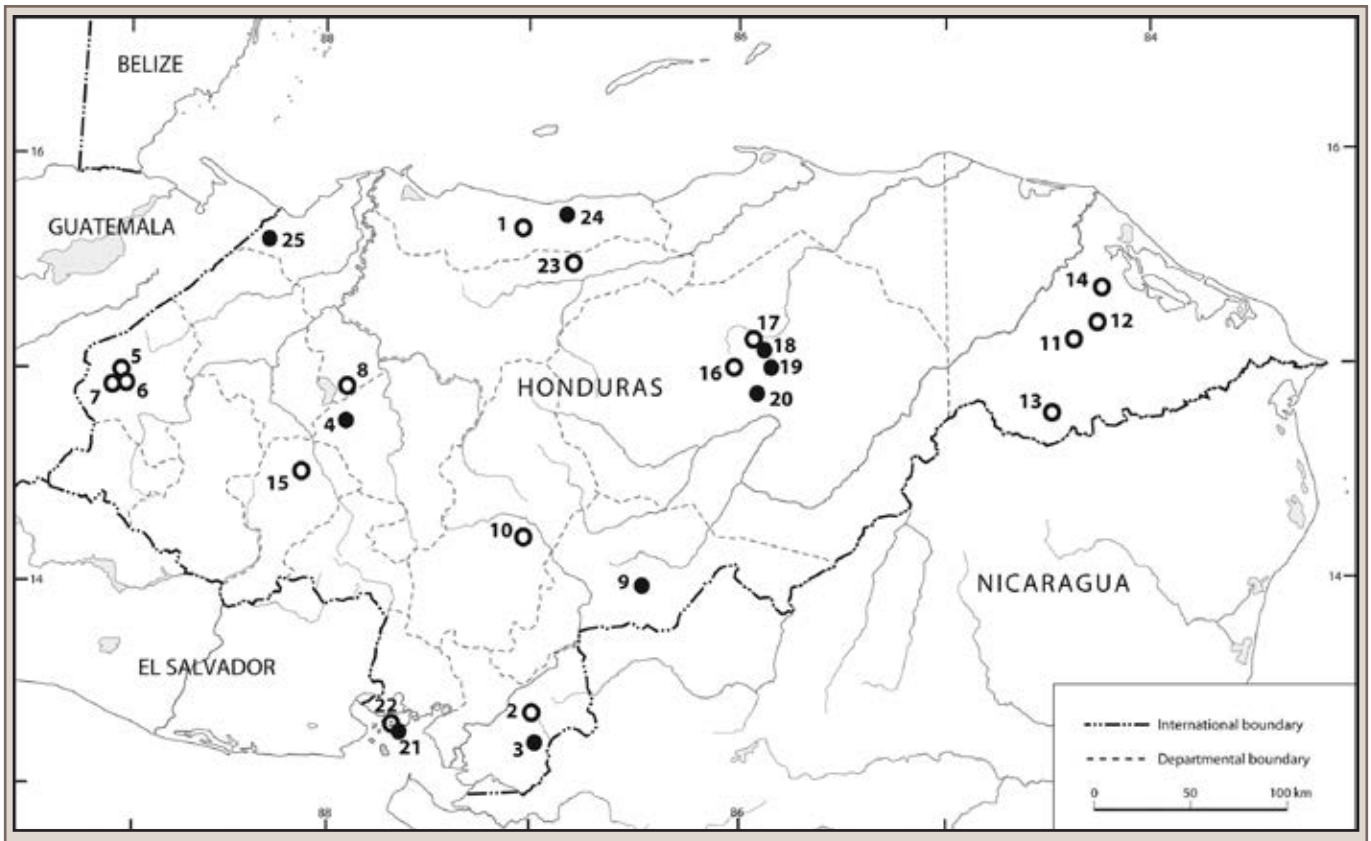

FIG. 1. Amphibian populations in Honduras analyzed for the presence of *Batrachochytrium dendrobatidis* (Bd; No. 1–23, see Table 1). Open circles: *Bd*-negative records; closed circles: Bd-positive records; No. 24: Pico Bonito National Park (Puschendorf et al. 2006), No. 25: Cusuco National Park (Kolby et al. 2009).

an initial denaturation step at 96°C for 5 min, followed by 50 cycles of 10 s at 96°C and 1 min at 60°C. We included negative controls and a positive control for each amplification. The qRT-PCR reactions were performed twice for each sample. A positive result consisted of a clearly sigmoid curve in both replicated samples. There were no discrepancies in the result of the two runs. All positive samples in the first run could be confirmed in the second run.

We found *Bd* in 16 of 114 (14%) specimens tested (Table 1). The *Bd*-positive animals represented ten frog species. No positive PCR amplifications occurred in the six salamanders and the one caecilian. Two of the five juvenile frogs tested were infected (*Craugastor lauraster*, *Lithobates vaillanti*) and the remainder were adults. The two frogs that were found dead were both *Bd*-positive (*C. laevissimus*; No. 18, Table 1); they showed no external defects (e.g., biting marks from predators). None of the specimens found alive showed clinical signs of infection with chytridiomycosis (e.g., external defects, lethargy, or loss of righting reflex).

Positive *Bd* records occurred in 7 of 23 (30%) localities sampled, with elevations that ranged from 10 m to 1850 m (Fig. 1, Table 1). We tested samples from six habitat formations (LMF, LDF, PWF, PMF, LMWF, and LMMF; see Table 1 for abbreviations) and *Bd*-infected frogs were found in all but the LMF habitats.

Our new records extend the known distribution of *Bd* more than 200 km southwards in Honduras from the northern Caribbean coast (Aanensen 2011; Olson et al. 2013). Together with the previous two known sites in the northern portion of Honduras (Puschendorf et al. 2006; Kolby et al. 2010), these results indicate that *Bd* occurrence is widespread throughout the country (Fig. 1), in various habitat formations, and from sea level to montane forest (Table 1).

These are the first published records of *Bd* for the following species: *Craugastor laevissimus, C. lauraster, Dendropsophus microcephalus, Lithobates forreri, L. vaillanti, Incilius luetkenii, I. valliceps,* and *Smilisca baudinii* (Aanensen 2011; Olson et al. 2013). The detection of *Bd* in *Rhinella marina* represents the first Honduran record in this species.

The two infected *Craugastor* species are listed as "Endangered" in the IUCN Red List of Threatened Species (Wilson et al. 2009; Cruz et al. 2010) because of their fragmented and restricted distributions. Most of their populations have declined or disappeared at elevations above 950 m during recent years and chytridiomycosis has been assumed a possible cause. Our data confirm for the first time that *Bd* occurs in populations of both species at the upper elevations of their respective altitudinal ranges (Table 1). Also the widespread frog *Lithobates maculatus* has disappeared in recent years from certain localities, and deforestation and resulting water pollution are probably associated with this decline (Santos-Barrera et al. 2004). We suggest adding chytridiomycosis as one potential threat, because several studies, including ours, have confirmed the widespread presence of *Bd* in this species (Puschendorf et al. 2006; Felger et al. 2007; Kolby et al. 2010).

Due to the opportunistic nature of our study, sampling sizes are too small and too scattered to estimate the effect of *Bd* on amphibian diversity in Honduras. Further research is needed to investigate the reason for the apparent decline in Honduran amphibian populations in addition to the most obvious and unregulated vast destruction of the habitats by the human population.

TABLE 1. Amphibian species sampled for *Batrachochytrium dendrobatidis* in Honduras. Compare No. with Fig. 1. Abbreviations used in the text and in the table: PN = Parque Nacional, LMF = Lowland Moist Forest, LDF = Lowland Dry Forest, PWF = Premontane Wet Forest, PMF = Premontane Moist Forest, LMWF = Lower Montane Wet Forest, LMMF = Lower Montane Moist Forest (McCranie 2011, modified from Holdridge 1967).

HERPETOCULTURE NOTES

TESTUDINES — TURTLES

***CUORA MOUHOTII MOUHOTII* (Northern Keeled Box Turtle) and *C. BOURETTI* (Bourret's Box Turtle). CAPTIVE HYBRIDIZATION.** Although "*Cuora serrata*" was originally described as a subspecies of *C. galbinifrons* (Iverson and McCord 1992. Proc. Biol. Soc. Washington 105:433–439), it later received full species status (Fritz and Obst 1997. Zool. Abh. Staatl. Mus. Tierk. Dresden 49:261–279). In 2001 genetic studies showed that it is a hybrid between male *C. mouhotii* ssp. and female *C. galbinifrons* or *C. bourreti* (Parham et al. 2001. Anim. Conserv. 4:357–367; Stuart and Parham 2004. Mol. Phyl. Evol. 31:164–177). "*Cuora serrata*" is now considered a collective noun for hybrids between members of the *C. galbinifrons*-complex and *C. mouhotii* sensu lato. Consequently, questions arose on the origin of this hybrid and in 2003 the first discovery of a wild "*C. serrata*" on Hainan (China) was reported (Shi et al. 2005. Amphibia-Reptilia 26:377–381). This proved at least a wild occurrence, but the possibility of a captive origin could not be excluded. Until now, no records of captive hybridization between members of the *C. galbinifrons*-complex and *C. mouhotii* sensu lato have been reported. Even in Chinese turtle farms there are no such farm-produced specimens (Zhou et al. 2008. Reptilia 61:27–34).

Only a small number of imported "*C. serrata*" are known to be kept in Europe, less than 50 in the USA, and equal numbers in China and Japan. In recent years, several hobbyists have attempted to produce these hybrids, but successful breeding has been limited. However, reproductive events have occurred between "*C. serrata*" specimens on a few occasions (Philippen 2002. Schildkröten 9[4]:14–27; Philippen 2003. Schildkröten 10[1]:12–23; J. Barzyk, pers. comm.; B. Esser, pers. comm.; W. P. McCord, pers. comm; M. Reimann, pers. comm.) as well as between "*C. serrata*" and *C. mouhotii* (M. R. Theiler, pers. comm.). Interestingly, this proves that at least some "*C. serrata*" are reproductively fertile.

FIG. 1. Dorsal and ventral view of parental specimens (*Cuora m. mouhotii* [left], *C. bourreti* [middle]) and the hybrid offspring ("*C. serrata*" [right]).

In the following case, unintentional captive hybridization between a male *C. m. mouhotii* (169 mm SCL [straight carapace length]) and a female *C. bourreti* (156 mm SCL) occurred at the first author's residence. While temporarily housing these specimens together in 2005, several mating attempts were observed. On 9 April 2006, at least five months after the animals had been separated, a single egg (54.84 x 27.67 mm) was produced. The egg was incubated in a Jäger Kunstglucke FB 50 incubator at steady temperatures of 30°C for the first seven weeks and 28°C for the remaining period. After 81 days of incubation, the egg hatched on 26 June 2006. The hatchling measured 42.6 mm (SCL) and weighed 12 g. Remnants of a yolk sac were absent. Serrated hind marginals were clearly present as well as the dorsal and lateral keels (Fig. 1). These features are (nearly) absent in *C. bourreti* hatchlings (and other members within the *galbinifrons*-complex) and are more prominent in hatchlings of *C. mouhotii* sensu lato. At the age of eight years, the specimen has proven to be female. To our knowledge this is the first record of "*C. serrata*" being created in captivity from cross-breeding pure parental specimens. We emphasize that purposely hybridizing different taxa, especially those that are critically endangered, is undesirable and such events should be prevented in captivity.

We thank J. Wang for reviewing the first draft of this correspondence and M. Klerks for photo editing.

CROCODYLIA — CROCODILIANS

***CROCODYLUS INTERMEDIUS* (Orinoco Crocodile). PARENTAL BEHAVIOR.** In April 2014, we were filming a sequence about parental behavior in captive Orinoco Crocodiles for a natural history documentary. Four adults, three females and one male, were maintained in a 1280 m^2 (40 m x 32 m) enclosure at Wisirare Park (4.910397°N, 71.433817°W), Orocué, Casanare, Colombia. The females lay eggs almost every year and the eggs are removed and taken to the incubator room for hatching. On the first day of filming we buried a speaker, connected to a Samsung 3S via a long cable, in one of the artificial beaches and played previously recorded hatchling vocalizations. The female that usually nests on that beach responded to the stimulus and came out of the water to dig in the spot where the speaker was buried; suddenly

FIG. 1. Adult Orinoco Crocodile male digging in a beach in response to recorded hatchling vocalizations.

FIG. 2. Adult female Orinoco Crocodile holding a hatchling in her mouth prior to transferring it to the adult male parent.

the male emerged from the water and aggressively pushed the female into the water. Then, the male began to remove the sand with its fore leg (Fig. 1) until he found the speaker and then he returned into water.

The next day we dug another hole, in a different beach, in which we placed four hatchlings born in the incubator room, they were not covered with sand. After two hours the hatchlings were in the same place and the mother began to pick them up with her mouth (Fig. 2). She carried them into the water where she opened her mouth and released the hatchlings close to the male. The hatchlings swam towards the male (their father), who opened his mouth into which some of the hatchlings entered. Then the male took the hatchlings to a small cave where he released them. Male and female aggressively protected the hatchlings against us, so we had to rope and immobilized both adults to recover the hatchlings.

Nest opening and the carrying of young by adult females is widespread in crocodilians. For the Orinoco Crocodile, these behaviors in females have been suggested (Medem 1981. Los Crocodylia de Sur América Vol I. Los Crocodylia de Colombia. Univ. Nac. De Colombia. Colombia. 270 pp) and confirmed (Thorbjarnarson and Hernández 1993. J. Herpetol. 4:371–379). Nest opening and carrying of young by adult males has been reported for *Caiman crocodilus*, *Crocodylus niloticus*, *C. novaeguineae* and *O. tetraspis* (for a review see Shine 1988. *In* Gans and Huey [eds.], Biology of the Reptilia vol. 16A, pp. 275–300. Alan R. Liss, New York).

To our knowledge, there are no reports of active male parental care for *C. intermedius*, neither in the field nor in captivity. These observations, added to those in which an adult wild male Orinoco Crocodile took food, a dead capybara (*Hydrochoerus hydrochaeris*), to a female guarding its nest (R. Antelo, pers. obs. 2008), suggest that male parental care in this species is far more complex than previously known. In addition these behaviors are more related to birds or mammals than to reptiles.

We thank Jorge Londoño and Alejandro Olaya of Palmarito Casanare Foundation and Francisco Forero of Ecoplanet Foundation for economic support, Richard Kirby for the pictures and Darío Rincón for field assistance.

***CROCODYLUS RHOMBIFER* (Cuban Crocodile). AGGRESSIVE BEHAVIOR.** A male and two female *Crocodylus rhombifer* are exhibited at the Smithsonian National Zoological Park. The females differ in size by approximately 20 kg. The male (ca. 45 years old) and the smaller female (ca. 33 years old) were both hatched in captivity, whereas the larger female was wild-caught and imported to the United States in 1962. These three animals have been housed together for over a decade in an exhibit measuring approximately 72 m^2. A pool measuring around three meters deep covers approximately half of the exhibit. The male copulates with both females seasonally and in the past three years both have nested and produced eggs. Eggs are removed from the exhibit for artificial incubation and animal keeper staff intentionally destroys nests within days of deposition to reduce the possibility of nest-guarding aggression. The smaller female typically nests in mid-April and the larger female in late April to early May.

Aggressive interactions were observed between the two female *C. rhombifer* following oviposition by both females in 2013 and 2014, with the first observed agonistic behavior occurring in May 2013. Using terminology described by Garrick et al. (1978. Bull. Am. Mus. Nat. Hist. 160:153–192) for *Alligator mississippiensis*, *C. acutus* and *C. niloticus*, the observed social interactions between the two female *C. rhombifer* are described below.

In 2013, oviposition took place on 19 April for the smaller female and 1 May for the larger female. On 29 May the larger female was seen on land in an inflated posture as it bellowed toward the smaller female, who then responded by standing erect from a relaxed position. The smaller female gave a deep grunt, which was shorter in duration and lower in pitch than the larger female's vocalization. Initiated by the larger female whose mouth was agape, the animals then began to circle one another. After a complete circle, the larger female lowered its head with its mouth agape and lunged at the smaller female. Although it appeared to be aiming to bite the smaller female's front leg, the bite occurred on the head. Both crocodiles had their mouths open when the larger female snapped onto the smaller female's head and then released. Following this contact, the smaller female retreated into the pool as the larger female followed. No further aggression was seen at this point. The male remained resting on land during the interaction, and was not involved in this display. This type of interaction was observed on multiple occasions in 2013.

A similar interaction was observed on 18 May 2014, but was shorter in duration than the interactions observed the previous year. In 2014, eggs were laid on 21 April and 10 May by the smaller and larger females, respectively. Eight days after the eggs were removed and the nests destroyed, the larger female was observed exiting the pool and approached the smaller

ILLUSTRATION BY KIM LOVICH

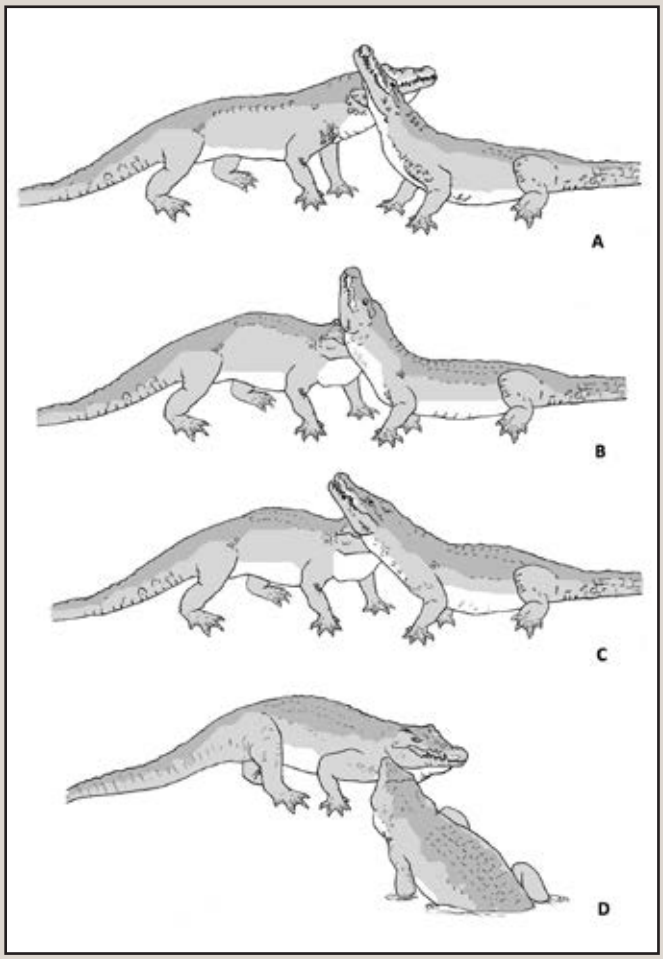

FIG. 1. An illustration of the aggressive interaction observed between two female *Crocodylus rhombifer* in 2014 at the Smithsonian National Zoological Park.

female, who was resting on land in the vicinity of the larger female's nest site. The smaller female then went from a resting position to an inflated position with its back arched and the head angled upward, and let out a low growl (Fig. 1A). The larger female continued to approach the smaller female, who let out two additional growls approximately 25 seconds apart (Fig. 1B). The larger female then used its snout to push the smaller female (Fig. 1C) off land into the pool, and then lowered into a resting position (Fig. 1D). The male remained in the pool for the duration of this interaction, which lasted 73 seconds.

The density of animals housed together in captive environments can affect dominance hierarchies (Barker et al. 1979. Copeia 1979:466–471) and the frequency with which aggressive interactions occur (Wilson 1975. Sociobiology: The New Synthesis. Harvard University Press, Cambridge, Massachusetts. 697 pp.; Arena and Warwick 1995. *In* Warwick et al. [eds.], Health and Welfare of Captive Reptiles, pp. 263–283. Chapman and Hall, London). The aggressive interactions seen between these two female *C. rhombifer* are most likely nest-guarding behaviors as they have only been observed during the month following nesting. Females of *C. acutus, C. niloticus* and *A. mississipiensis* utilize growls and grunts when defending their nests (Garrick and Lang 1977. Am. Zool. 17:225–239). Since the animals are not observed 24 h a day, it is also possible that these interactions occurred more frequently than they were witnessed. Inflated posturing to communicate territoriality has been seen in female *A. mississipiensis*, but not *C. niloticus* or *C. acutus* (Garrick and Lang 1977, *op. cit.*). These types of social interactions for *C. rhombifer* have not been widely reported on, and may have captive management implications when developing housing and breeding recommendations for crocodilians in captivity.

We thank Rick Quintero for his assistance with crocodilian husbandry, and James B. Murphy and Robert Mendyk for their valuable feedback.

***CROCODYLUS RHOMBIFER* (Cuban Crocodile). PLAY BEHAVIOR.** Behavior identified as play has only recently been confidently attributed to reptiles, but has been increasingly found to occur when the following abbreviated definition is applied: "Play is repeated, seemingly non-functional behavior differing from more adaptive versions structurally, contextually, or developmentally, and initiated when the animal is in a relaxed, unstimulating, or low stress setting" (Burghardt 2014. Anim. Behav. Cogn. 1:90–98). Object play is the most common type of play reported in crocodilians and is being reported more as captive crocodilians are being provided with unique objects as part of their captive enclosures (Dinets 2015. Anim. Behav. Cogn. 2:49–55).

At the Smithsonian National Zoological Park, a male and two female Cuban Crocodiles, *Crocodylus rhombifer*, are housed on exhibit between a pair of *C. rhombifer* (left) and a female *Gavialis gangeticus* (right) in the Reptile Discovery Center (Fig. 1). These enclosures are divided by metal bar fencing. In July 2014, three cinderblocks were placed along the left fence line in the middle *C. rhombifer* exhibit as a part of an operant conditioning program. The blocks were painted; one black, one white, and one normal gray coloration. The next morning, the black block, weighing 14.24 kg, was found in the pool approximately 4.1 m from its original placement in the exhibit (Fig. 2). Over the next few months the cinderblocks were placed in the exhibit in various orders along the fence line. The black block was consistently found in the pool the days following introduction. When a new black block, weighing 18.1 kg, replaced the old, this block ended

FIG. 1. The front of the three crocodilian exhibits showing the metal bar fencing dividing the enclosures

FIG. 2. The middle crocodilian exhibit with two of the three blocks along the fence line and the black block in the pool where the crocodile(s) moved it.

up in the pool as well, along with the old black block that had not yet been removed. The crocodiles were never seen with the blocks, except for one instance when a keeper servicing the left *C. rhombifer* exhibit saw the male pick up the block and drop it in the pool. The black block was moved from the fence line to the pool by the crocodile(s) seven times in a two-month period.

On 24 October 2014, three black blocks were placed along the fence line. The other two blocks were freshly painted black. Two days later the lightest-colored block, which was faded from being in use since July, was in the pool. This block was left in the pool and no changes were made to the exhibit. At this point the crocodiles were never seen with the blocks, except for one instance when a keeper servicing the left *C. rhombifer* exhibit saw the male pick up the block and drop it in the pool. On 27 October, the male, 46 years old, was seen in the pool with a darker block in his mouth. His lower jaw was through the middle of the block and he appeared to be using the block to sink to the bottom of the pool. Occasionally he would surface, arching his back, head and tail up and would blow bubbles similar to the courtship behavior seen with these animals. Still holding the block an hour later, he was shaking it side to side under water and then rolled with the brick in his mouth. At this point, both of the females became interested in this male's behavior and approached. He attempted to keep the block away from the females, swimming away from them when they approached, demonstrating what appeared to be possessive behavior. Eventually one female mouthed at the block and bumped heads with the male several times under water until the male dropped the block. The block was left untouched until a keeper removed it from the pool days later. Overall, the male had possession of the block for three hours. Part of this behavior was video recorded.

Initially it was thought that the male *C. rhombifer* were combatting through the fence line and the black block was unintentionally moved as a result of these aggressive displays. It was not until the animal was seen carrying and manipulating the cinderblock that this was reconsidered. Keepers investigated the crocodile's specific interest in the black block by first checking the temperature of each block in the exhibit. The temperature differences were minor, with the black block being only 0.3° C warmer than the other two blocks. Another hypothesis was that the brick had some olfactory cue that the crocodile was drawn to, but this was disproven by placing novel black blocks in the enclosure. The sequence of the blocks against the fence also seemed to be insignificant. Three different black blocks were used over the four-month period.

Based on the definition given previously, we conclude that the male *C. rhombifer* was indeed playing with this cinderblock. Play behavior has been documented more prominently in mammals and birds and may be less apparent in reptiles due to physiological and natural history constraints (Burghardt 2005. The Genesis of Animal Play: Testing the Limits. MIT Press, Cambridge, Massachusetts. 501 pp.). Although rarely documented, play behavior in crocodilians may be frequent, including in the wild, but not recognized as such and thus deemed insignificant (Lazell and Spitzer 1977. Copeia 1977:188; Dinets 2015, *op. cit.*).

SQUAMATA — SNAKES

***LAMPROPELTIS ELAPSOIDES* (Scarlet Kingsnake). SIZE RECORD.** On 23 April 2014, a male *Lampropeltis elapsoides* measuring 740 mm TL (632 mm SVL) died after at least eight years in captivity. This exceeds the maximum reported size of 686 mm TL (Boundy 1995. Bull. Chicago Herpetol. Soc. 30:109122). The snake was caught as an adult (ca. 400 mm TL) near Woodville, Wakulla Co., Florida, USA. The snake is deposited in the Florida Museum of Natural History (UF 174934).

Verified by David Laurencio. Auburn University Museum of Natural History (AUM AHAP-D 870 [digital photograph]). New county record (Hulse et al. 2001. Amphibians and Reptiles of Pennsylvania and the Northeast. Cornell University Press, Ithaca, New York).

CHRISTOPHER J. THAWLEY, Department of Biology, Pennsylvania State University, 208 Mueller Laboratory, University Park, Pennsylvania, 16802, USA (e-mail: cthawley@gmail.com); **FERN GRAVES**, Department of Entomology, Pennsylvania State University, 501 ASI Building, University Park, Pennsylvania 16802, USA (e-mail: fbg106@psu.edu).

***NECTURUS MACULOSUS LOUISIANENSIS* (Red River Mudpuppy)**. USA: OKLAHOMA: Pittsburg Co.: Mud Creek at vicinity of Eufaula Lake off St. Hwy. 31, 1.6 km NE of Richville (34.948502°N, 95.662487°W; WGS 84). 25 February 1988. R. Welsh. Verified by S. E. Trauth. Arkansas State University Museum of Zoology, Herpetological Collection (ASUMZ 33332). New county record (Oklahoma Biological Survey, Distribution of Oklahoma Amphibians and Reptiles by Recorded Sightings [DOKARRS Search], http://www.biosurvey.ou.edu/dokarrs_srch.html; Sam Noble Oklahoma Museum of Natural History Reptile Database [SNOMNH Search], http://www.snomnh.ou.edu). Interestingly, the SNOMNH houses only 14 specimens of *N. m. louisianensis* from Oklahoma in their collection (SNOMNH 2015. *op. cit.*). Specimen previously collected and cataloged into the ASUMZ without permit information.

CHRIS T. McALLISTER, Science and Mathematics Division, Eastern Oklahoma State College, Idabel, Oklahoma 74745, USA, e-mail: cmcallister@se.edu.

ANURA — FROGS

***ALLOBATES TRILINEATUS* (Three-Striped Rocket Frog)**. BRAZIL: ACRE: Municipality of Rio Branco: Rio Branco (9.957222°S, 67.873611°W; WGS 84), 170 m elev. 1 November 2005. Moisés Barbosa de Souza, Elaine Nascimento and Vanessa M. Souza. Herpetological Collection of Universidade Federal do Acre (UFAC-RB 3550). 27 October 2009. Paulo Roberto Melo-Sampaio and Thays de Andrade Farias. UFAC-RB 46054615. Municipality of Senador Guiomard (10.0822°S, 67.06258°W; WGS 84), 180 m elev. 31 July 1985. Adão J. Cardoso. UFAC-RB 0160, 01620164. Municipality of Sena Madureira (9.151528°S, 68.543167°W; WGS 84), 154 m elev. 4 December 2010. Paulo Roberto Melo-Sampaio, Hemerson Gomes da Silva, and Manoel Emir Canizo Dantas. UFAC-RB 47034704, 5557. All specimens verified by Moisés Barbosa de Souza. This species was previously known from the Amazonian lowlands from Ecuador, Peru, and northwestern Bolivia. Within

Bolivia this species is known from Beni, Cochabamba, La Paz, Pando and Santa Cruz departments (Köhler and Lötters 1999. Bonn. Zool. Beitr. 48:259273; De la Riva et al. 2000. Rev. Esp. Herpetol. 14:19164; Kohler 2000. Bonn. Zool. Monogr. 48:1243), and in Peru is known from Amazonas, Huánuco, Loreto, Madre de Dios, and Puno (Grant and Rodríguez 2001. Am. Mus. Novit. 3355:1–24). First country record from the Acre state approximately 280 km from the eastern edge of the previously known range from Rio Curanja, Balta in Peru (Grant and Rodríguez 2001, *op. cit.*) and 160 km northern from Cobija, Pando in Bolivia (Köhler and Lötters 1999, *op. cit.*). Specimen collected under an approved SISBIO permit (#19347-1).

***ELEUTHERODACTYLUS CYSTIGNATHOIDES* (= *SYRRHOPHUS CYSTIGNATHOIDES*) (Rio Grande Chirping Frog)**. USA: TEXAS: Fort Bend Co.: Missouri City (29.559254°N, 95.577707°W; WGS 84), 20 m elev. 16 February 2014. Marissa R. Hickel, Zachary C. Adcock, Shawn F. McCracken, and Michael R. J. Forstner. Verified by Toby J. Hibbitts. Biodiversity Research and Teaching Collections (TCWC 100266). New county record (Dixon 2013. Amphibians and Reptiles of Texas: with Keys, Taxonomic Synopses, Bibliography, and Distribution Maps. Texas A&M University Press, College Station, Texas. 447 pp.). This species is documented from neighboring Austin, Brazoria, and Harris counties (Dixon 2013, *op. cit.*). The nearest previously documented record is ca. 20 km to the NE in Harris Co. (TCWC 69332). Adult specimen (21.9 mm SUL) discovered in moist leaf litter under a potted plant in a residential neighborhood. Specimen collected under a Scientific Collecting Permit (SPR-0102-191) issued to MRJF by Texas Parks and Wildlife Department.

MARISSA R. HICKEL (email: mrh4@txstate.edu), **ZACHARY C. ADCOCK**, **SHAWN F. McCRACKEN**, and **MICHAEL R. J. FORSTNER**, Department of Biology, Texas State University, 601 University Drive, San Marcos, Texas 78666, USA.

***ELEUTHERODACTYLUS CYSTIGNATHOIDES* (= *SYRRHOPHUS CYSTIGNATHOIDES*) (Rio Grande Chirping Frog)**. USA: TEXAS: Robertson Co.: ca. 11 km E of Hearne (30.881331°N, 96.475100°W; WGS 84), 122.8 m elev. 21 August 2014. Andrew R. MacLaren, Zachary C. Adcock, Shawn F. McCracken, and Michael R.J. Forstner. Verified by Toby J. Hibbitts. Biodiversity Research and Teaching Collections (TCWC 100264, 100265). New county record (Dixon 2013. Amphibians and Reptiles of Texas: with Keys, Taxonomic Synopses, Bibliography, and Distribution Maps. Texas A&M University Press, College Station, Texas. 447 pp.). The nearest previously documented record is ca. 35 km SE in Brazos Co. (TCWC 84165). We consider this to document the continued expansion of this taxon outside its normal distribution in Texas. Species first detected during anuran chorus surveys on 22 May 2014 and on subsequent dates. Two adult specimens (20.0 mm and 18.6 mm SUL) collected and numerous additional individuals were observed during bucket trap and artificial cover object surveys on the property which is located on the Carrizo Sands outcrop in Post Oak savannah habitat. Specimens collected under a Scientific Collecting Permit (SPR-0102-191) issued to MRJF by Texas Parks and Wildlife Department.

***GASTROPHRYNE OLIVACEA* (Western Narrow-mouthed Toad)**. USA: TEXAS: Rockwall Co.: Junction of FM 1141 and N Country Ln (32.960341ºN, 96.433210ºW; WGS 84). 21 May 2013. Connor S. Adams. Verified by James R. Dixon. Biodiversity Research and Teaching Collections (TCWC 97652). New county record (Dixon 2013. Amphibians and Reptiles of Texas: with Keys, Taxonomic Synopses, Bibliography, and Distribution Maps. Texas A&M University Press, College Station, Texas. 447 pp.). Known from neighboring Collin, Dallas, Hunt, and Kaufman counties in Texas (Dixon 2013, *op. cit.*). Specimen collected under a Texas Parks and Wildlife Scientific Collecting Permit (SPR-0506-662) issued to TJH.

TOBY J. HIBBITTS (e-mail: thibbitts@tamu.edu) and **CONNOR S. ADAMS**, Texas Cooperative Wildlife Collections, Department of Wildlife and Fisheries Sciences, Texas A&M University, 2258 Tamu, College Station, Texas 77843-2258, USA.

***GASTROTHECA FISSIPES* (Marsupial Tree Frog)**. BRAZIL: SERGIPE: Municipality of Pirambu: Aguilhadas Locality (10.69281°S, 36.84061°W; WGS 84), 76 m elev. 23 April 2014. Maria A. Xavier and Eduardo J.R. Dias. Verified by U. Caramaschi. Herpetological Collection of Laboratório de Biologia e Ecologia de Vertebrados, Universidade Federal de Sergipe, Itabaiana, Sergipe, Brazil (LABEVA 1057). Adult female found in a fragment of *restinga* habitat ca. 1600 h within a bromeliad, releasing 18 froglets from its dorsal pouch. This species is endemic to Brazil and is previously known from the states of Pernambuco, Alagoas, and southern Bahia (Izecksohn et al. 2009. Arq. Mus. Nac. 67:81–91; Mendes et al. 2012. Zootaxa 3312:62–64; Teixeira Jr. et al. 2012. Zootaxa 3437:1–23). First state record and fourth specimen from northeastern Brazil, extending the species distribution ca. 487 km S from the type locality, in Igarassú, Pernambuco (Izecksohn et al. 2009, *op. cit.*) and ca. 238 km from nearest locality to the south, at Maceió, State of Alagoas (Teixeira Jr. et al. 2012, *op. cit.*). Specimen collected under SISBIO/ICMBio permit #6878-1.

***HYLA GRATIOSA* (Barking Treefrog)**. USA: TENNESSEE: McNairy Co.: Finger, 294 Sherry Lynn Drive (35.357800°N, 88.635583°W; WGS84). 2 May 1997. Brian P. Butterfield. Verified by A. Floyd Scott. Austin Peay State University Museum of Zoology (APSU 05543 [photographic voucher]). First county record (Redmond and Scott 1996. Atlas of Amphibians in Tennessee. Misc. Publ. No. 12, The Center for Field Biology, Austin Peay State University, Clarksville, Tennessee. 94 pp. Hard copy and Internet versions [http://www.apsu.edu/amatlas/]. Accessed 9 May 2015). Specimen collected on a residential window at a rural subdivision located in an oak/hickory forest. Voucher collected under a Tennessee Wildlife Resources Agency Permit (#1494).

BRIAN P. BUTTERFIELD, Freed-Hardeman University, 151 E. Main Street, Henderson, Tennessee 38340, USA; e-mail: bbutterfield@fhu.edu.

***INCILIUS NEBULIFER* (Gulf Coast Toad)**. USA: TEXAS: Rockwall Co.: 0.04 air km N of TX 66 at public boat ramp at the end of Willow Bend Rd (32.929079°N, 96.473736°W; WGS 84). 10 June 2012. Connor S. Adams. Verified by James R. Dixon. Biodiversity Research and Teaching Collections (TCWC 96961). New county record (Dixon 2013. Amphibians and Reptiles of Texas: with Keys, Taxonomic Synopses, Bibliography, and Distribution Maps. Texas A&M University Press, College Station, Texas. 447 pp.). Known from neighboring Dallas and Kaufman counties in Texas (Dixon 2013, *op. cit.*). Specimen collected under a Texas Parks and Wildlife Scientific Collecting Permit (SPR-0506-662) issued to TJH.

TOBY J. HIBBITTS (e-mail: thibbitts@tamu.edu) and **CONNOR S. ADAMS**, Texas Cooperative Wildlife Collections, Department of Wildlife and Fisheries Sciences, Texas A&M University, 2258 Tamu, College Station, Texas 77843-2258, USA.

***KALOULA PULCHRA* (Asiatic Painted Frog)**. PHILIPPINES: MARINDUQUE ISLAND: Marinduque Province: Municipality of Mogpoc, Barangay Villa Mendez (13.473889°N, 121.860833°E, WGS 84) 10 m elev. 29 December 2014. Don Ashley O. Malabana. Verified by Indraneil Das. Photographic voucher, Lee Kong Chian Natural History Museum, National University of Singapore, (ZRC[IMG] 1.76). This specimen is the first record for Marinduque Island. *Kaloula pulchra* is an introduced species and has previously been recorded on Cebu, Luzon, Mindanao, and Palawan (Sy et al. 2014. Herpetol. Rev. 45:276–277).

EMERSON Y. SY, Philippine Center for Terrestrial and Aquatic Research, 1198 Benavidez Street, Unit 1202, Tondo, Manila, Philippines (e-mail: emersonsy@gmail.com); **DON ASHLEY O. MALABANA**, 11 P. Villaster Street, Villa Mendez, Mogpog, Marinduque, Philippines.

***LEPTODACTYLUS FUSCUS* (Rufous Frog)**. BRAZIL: ACRE: Municipality of Tarauacá: Complexo Florestal do Gregório ponto 5 (7.943889°S, 71.535278°W; WGS 84), 225 m elev. 19 June 2006. Moisés Barbosa de Souza and Marilene Vasconcelos Silva. Verified by Moisés Barbosa de Souza. Herpetological Collection of Universidade Federal do Acre, Rio Branco, Acre, Brazil (UFAC-RB 4324). The species is found in savannas from Panama throughout South America, east of the Andes, south to southern Brazil, Bolivia, Paraguay, and northern Argentina (Frost 2014. Amphibian Species of the World: an Online Reference. Version 6.0. http://research.amnh.org/vz/herpetology/amphibia/; Sá et al. 2014. South Am. J. Herpetol. 9:S1–S128). In Brazil, this species is found in Amazonas, Bahia, Ceará, Distrito Federal, Goiás, Espírito Santo,

Maranhão, Mato Grosso, Mato Grosso do Sul, Minas Gerais, Pará, Pernambuco, Piauí, Rio de Janeiro, Rio Grande do Sul, Rondônia and Tocantins (Heyer 1978. Nat. Hist. Los Angeles Count. Sci. Bull. 29:184; Wynn and Heyer 2001. Trop. Zool. 14:255285; Lima et al. 2006. Guide of the frogs of Reserva Ducke Central Amazonia. Áttema Design Editorial, Manaus, Amazonas. 168 pp.; Silva et al. 2010. Sitientibus, Ser. Cienc. Biol. 7:334340). First state record extending the geographic distribution of *L. fuscus* ca. 890 km W from closest records in São Carlos, Municipality of Porto Velho, Rondônia and 480 km S to Belém do Solimões, Municipality of Tabatinga, Amazonas (Heyer 1978, *op. cit.*).

PAULO ROBERTO MELO-SAMPAIO, Programa de Pós-graduação em Zoologia, Museu Nacional, Quinta da Boa Vista, s/n Rio de Janeiro, RJ - CEP: 20940-040 – Brazil; e-mail: prmelosampaio@gmail.com.

***LEPTODACTYLUS THOMEI* (Povoação White-lipped Frog).** BRAZIL: MINAS GERAIS: Municipality of Periquito: Fazenda Coqueria (19.10°S, 42.18°W; SAD 69), 194 m elev. 19–23 November 2008. R. Filogonio and M. A. S. Canelas. Verified by C. S. Cassini. Museu de Ciências Naturais, Pontifícia Universidade Católica de Minas Gerais, Belo Horizonte, Minas Gerais, Brazil (MCNA 11032, 11034, 11035, 11066–11068). *Leptodactylus thomei* is a Brazilian species found in Espírito Santo (Povoação, Mimoso do Sul, and probably Governador Lindemberg), and possibly Bahia (Ilhéus) states (Almeida and Angulo 2006. Zootaxa 1334:1–25; Almeida and Gasparini 2010. Checklist 6:13–14). First state record that extends the known distribution ca. 240 km NW from Mimoso do Sul and ca. 565 km SW from Ilhéus and is the most inland locality of the species. Permissions were conceded by Instituto Brasileiro do Meio Ambiente e Recursos Naturais Renováveis (IBAMA) under licenses nº141/2008 NUFAS/MG Process IBAMA nº02015.011675/2007-25, and nº516/2009 NUFAS/MG Process IBAMA nº02015.011675/2007-26.

***LITHOBATES CAPITO* (Gopher Frog).** USA: FLORIDA: Flagler Co: Pellicer Creek Conservation Area (29.64744°N, 81.26667°W; WGS 84). 18 July 2014. Kevin M. Enge. Verified by Kenneth L. Krysko. Florida Museum of Natural History (UF 173547, digital photographic voucher). First county record (Krysko et al. 2011. Atlas of Amphibians and Reptiles in Florida. Final report, Florida Fish and Wildlife Conservation Commission, Tallahassee, Florida. 524 pp.). Juvenile observed at 1520 h inside a Gopher Tortoise (*Gopherus polyphemus*) burrow in sandhill habitat where planted *Pinus clausa* had been harvested eight months earlier.

KEVIN M. ENGE (e-mail: kevin.enge@myfwc.com) and **ANNA L. FARMER**, Florida Fish and Wildlife Conservation Commission, 1105 S.W. Williston Road, Gainesville, Florida 32601, USA; **BRIAN W. EMANUEL**, St. Johns River Water Management District, P.O. Box 1429, Palatka, Florida 32178, USA.

***PRISTIMANTIS ORPHNOLAIMUS* (Lago Agrio Robber Frog).** PERU: LORETO: Province of Maynas: Santa Cruz Forest Preserve (3.513797°S, 73.182372°W; WGS 84), 100 m elev. 17 January 2015. Emerson Torres Pacaya and Marisa Ishimatsu. Verified by Santiago R. Ron. University of Kansas Digital Archives, Lawrence, Kansas (KUDA 12336–12338). An adult specimen was discovered after dark approximately 3.5 m up on a spiny palm frond (*Bactris riparia*) over hanging a creek. This arboreal species was previously known from only a handful of specimens at six localities in primary forest of the eastern Ecuadorian provinces of Orellana, Pastaza, and Sucumbíos, from 250350 m in elevation (Lynch 1970. Proc. Biol. Soc. Washington 83:221226; Almendáriz et al. 2004. *Pristimantis orphnolaimus*. www.iucnredlist.org; 7 February 2015). New country record (Almendáriz et al. 2004, *op. cit.*) extending the range of this poorly known taxon 375 km SE from the easternmost record in Ecuador (0.97839°S, 75.42569°W, Museo de Zoologia QCAZ: QCAZA 55245), extends the minimum known elevation to 100 m, and represents the first record outside Ecuador. The area of Santa Cruz Forest Reserve where this specimen was discovered consists of a mixture of primary forest and 10- to 20-year-old secondary growth forest, suggesting the species may be more tolerant to anthropomorphic disturbances than previously suspected (McCracken and Forstner 2014. PLOS ONE 9:e85470).

***RHINELLA AMBOROENSIS* (Cochabamba Toad).** BOLIVIA: SANTA CRUZ: Province of Manuel Maria Caballero: Verdecillo (17.836397°S, 64.570981°W; WGS 84), 2181 m elev. 29 January 2012. Ronald Sosa and Lorenzo Braga. Verified by Lucindo Gonzales. Museo Historia Natural Noel Kempff Mercado, Santa Cruz, Bolivia (MNKA 10890). Adult found at night at 2230 h. Los Remates (17.880707°N, 64.344516°W; WGS 84), 2053 m elev. 9 February 2012. Ronald Sosa and Lorenzo Braga. Verified by Lucindo Gonzales. MNKA 10903. An adult male and female found in amplexus in a stream. Species previously known only from its type locality, Rio Chua Kocha Parque Nacional Carrasco, Province of Carrasco, Cochabamba (Harvey and Smith 1993. Proc. Biol. Soc. Washington 106:442–449). First record for the department of Santa Cruz, extending the known distribution 43 km SE from its type locality, and extends its elevational range from 2150 m to 2181 m.

This work was supported by a grant from the Rufford Foundation. Specimen collected under a Ministerio de Medio Ambiente y Agua (MAyA) – Estado Plurinacional de Bolivia permit (Resolucion Administrativa VMABCC N026/09) issued to Institucion Cientifica Autorizada (ICA) – Museo de Historia Natural Noel Kempff Mercado.

***SCAPHIOPUS HURTERII* (Hurter's Spadefoot).** USA: TEXAS: Guadalupe Co.: ca. 12 km S of Seguin, due east of State Highway 123, at private ranch gate (29.428875°N, 97.950468°W; WGS 84), 201 m elev. 20 December 2013. Michelle E. Curtis, Zachary C. Adcock, Rebekah J. Rylander, and Thomas R. Simpson. Verified by Toby J. Hibbitts. Biodiversity Research and Teaching Collections (TCWC 100268). New county record (Dixon 2013. Amphibians and Reptiles of Texas: with Keys, Taxonomic Synopses, Bibliography, and Distribution Maps. Texas A&M University Press, College Station, Texas. 447 pp.). This record fills a distributional gap among Bexar, Wilson, Gonzales, and Caldwell counties (Dixon 2013, *op. cit.*). The nearest previously documented record is ca. 38 km to the SW in Wilson Co. (TCWC 79028). Adult female specimen (60.15 mm SUL; 29.5 g) discovered injured on a dirt road near the ranch gate. Additional specimen (not vouchered) captured in a Sherman trap on the same day during a small mammal survey of the property. Property is located on the Carrizo Sands outcrop in Post O-ak savannah habitat. Specimen collected under Scientific Collecting Permit (SPR-0993-638) issued to TRS by Texas Parks and Wildlife Department.

***SCINAX NASICUS* (Lesser Snouted Treefrog).** BRAZIL: RIO DE JANEIRO: Municipality of Porto Real: Porto Real (22.42°S, 44.28°W; SAD 69). 17 November 2013. J. Pederassi. Verified by U. Caramaschi. Museu Nacional, Rio de Janeiro, Brazil (MNRJ 87535–87537). This species is known to occur in Bolivia, Paraguay, Uruguay, Argentina, and Brazil. Within Brazil it occurs in the states of Mato Grosso, Mato Grosso do Sul, Southern Goiás, Western of Minas Gerais, São Paulo, Paraná, Santa Catarina and Rio Grande do Sul, but not previously detected in the East of Serra da Mantiqueira or closer than 230 km from the Atlantic ocean (Natale and Herrera 2006. Herpetol. Rev. 37:360; Carezzano and Cabrera 2010. Check List 6:390–391; IUCN 2013. Red List of Threatened species. Version 2013.2. http://www.iucnredlist.org/details/55980/0; Frost 2014. Amphibian Species of the World: an Online Reference. Version 6.0. http://research.amnh.org/vz/herpetology/amphibia/). First state record, increasing its occurrence beyond the Mantiqueira ridge and at least 160 km SE from its nearest occurrence in the State of Minas Gerais (Municipality of Alfenas). This specimen also represents the nearest occurrence to the Atlantic Ocean in the previously Floresta Atlântica domain, which is now climatically more related to Cerrado domains due to deforestation.

TESTUDINES — TURTLES

***APALONE SPINIFERA* (Spiny Softshell).** USA: TENNESSEE: Sullivan Co.: Steele Creek Park Lake, Bristol, captured along the shoreline in a cove approximately 80 m NW from Steele Creek Lake dam (36.563956°N, 82.227629°W; WGS 84). 19 July 2004. Chris O'Bryan. Verified by A. Floyd Scott. Austin Peay State University Museum of Zoology (APSU 19542, photo voucher). New county record (Scott and Redmond 2008 [latest update: 12 January 2015]. Atlas of Reptiles in Tennessee. The Center for Field Biology, Austin Peay State University, Clarksville, Tennessee. Available at http://www.apsu.edu/reptatlas/, accessed 20 January 2015). An adult female (carapace length: 34.9 cm; plastron length: 23.7 cm; 3750 g), was captured using a finger-throated hoop trap baited with perch and chicken gizzards. BR and JWC had unvouchered records from June–July 1970, and MKH and CJO had unvouchered records from 1997–2003 in the same cove. Specimen collected under Tennessee Wildlife Resource Agency Scientific Collection Permit (#1384) issued to CJO and MKH.

***KINOSTERNON SUBRUBRUM* (Eastern Mud Turtle)**. USA: TEXAS: Rockwall Co.: 0.50 km N of jct TX 66 on FM 549 (32.940741°N, 96.417668°W; WGS 84). 26 May 2013. Connor S. Adams. Verified by James R. Dixon. Biodiversity Research and Teaching Collections (TCWC 97658). New county record (Dixon 2013. Amphibians and Reptiles of Texas: with Keys, Taxonomic Synopses, Bibliography, and Distribution Maps. Texas A&M University Press, College Station, Texas. 447 pp.). Known from neighboring Collin, Dallas, Hunt, and Kaufman counties, Texas (Dixon 2013, *op. cit.*). Specimen collected under a Texas Parks and Wildlife Scientific Collecting Permit (SPR-0506-662) issued to TJH.

TOBY J. HIBBITTS (e-mail: thibbitts@tamu.edu) and **CONNOR S. ADAMS**, Texas Cooperative Wildlife Collections, Department of Wildlife and Fisheries Sciences, Texas A&M University, 2258 Tamu, College Station, Texas 77843-2258, USA.

***STERNOTHERUS ODORATUS* (Eastern Musk Turtle)**. USA: TEXAS: Jackson Co.: 23 km NW of Edna on SH 111 (29.08363°N, 96.72182°W; WGS 84). 3 August 2014. Romey L. Swanson. Verified by Travis J. LaDuc. Texas Natural History Collections (TNHC 93300). New county record (Dixon 2013. Amphibians and Reptiles of Texas: with Keys, Taxonomic Synopses, Bibliography, and Distribution Maps. Texas A&M University Press, College Station, Texas. 447 pp.). A single adult (carapace length: 85.00 mm; 90.2 g) was collected live by hand from HW 111. The collection site lies approximately 1400 m from the Navidad River. Aerial imagery displays several earthen ponds within the area between the river and collection site; the closest occurs 60 m from the road. *Sternotherus odoratus* has been previously confirmed within three of five adjacent counties (Matagorda, Colorado, and Victoria; Dixon 2013, *op. cit.*).

ROMEY L. SWANSON (e-mail: romeyswanson@gmail.com) and **J. ERIC LEE**, Balcones Wildlife Management, New Braunfels, Texas 78130, USA (e-mail: ericlee@balconeswildlife.com).

***TRACHEMYS SCRIPTA* (Pond Slider)**. USA: TEXAS: Ector Co.: UTPB Duck Pond on University of Texas Permian Basin campus grounds (31.892115°N, 102.325071°W; WGS 84). 24 June 2012. Connor S. Adams and Drew E. Dittmer. Verified by James R. Dixon. Biodiversity Research and Teaching Collections (TCWC 96956). New county record (Dixon 2013. Amphibians and Reptiles of Texas: with Keys, Taxonomic Synopses, Bibliography, and Distribution Maps. Texas A&M University Press, College Station, Texas. 447 pp.). Known from neighboring Midland Co., Texas (Dixon 2013, *op. cit.)*.

This specimen was collected during research on *Sceloporus arenicolus* with funding from Texas Comptrollers Office and under a Texas Parks and Wildlife Scientific Collecting Permit (SPR-0506-662) issued to TJH.

TOBY J. HIBBITTS (e-mail: thibbitts@tamu.edu) and **CONNOR S. ADAMS**, Texas Cooperative Wildlife Collections, Department of Wildlife and Fisheries Sciences, Texas A&M University, 2258 Tamu, College Station, Texas 77843-2258, USA.

SQUAMATA — LIZARDS

***ANOLIS CHLOROCYANUS* (Northern Green Anole)**. DOMINICAN REPUBLIC: PEDERNALES PROVINCE: Laguna de Oviedo, northeastern border of Jaragua National Park, 4 airline km E of Oviedo (17.802429°N, 71.362881°W; determined from Goggle Earth). 12 March 2013. Miguel A. Landestoy. Verified by Jonathan Losos. Museum of Comparative Zoology (MCZ-R-191169, photographic voucher). First record for Pedernales, and 53 airline km SW of Barahona, the previous southernmost extent for the species on Hispaniola's south paleo-island (Powell et al. 1991. Herpetol. Rev. 22:134–135), where it is reported to hybridize with *A. coelestinus* (Garcia et al. 1994. Carib. J. Sci. 30:279281). A second adult male was found nearby in the vicinity of Oviedos town park (17.800573°N, 71.399502°W; determined from Goggle Earth). 26 April 2013. Miguel A. Landestoy. Verified by Jonathan Losos. MCZ-R-191170 (photographic voucher). *Anolis chlorocyanus* is widespread on Hispaniola's north paleo-island, other than in very xeric areas (Henderson and Powell 2009. Natural History of West Indian Reptiles and Amphibians. University of Florida Press, Gainesville, Florida. 495 pp.). Its occurrence around Laguna de Oviedo could be due to lizards colonizing building materials used for construction of Jaragua National Park visitor center or with transported garden plants and soils into the town of Oviedo; both *A. coelestinus* and *A. chlorocyanus* now occur syntopically, at least around the visitor center.

MIGUEL A. LANDESTOY, Sociedad Ornitologica de la Hispaniola, Apto. 401 Res. Las Galerías, Calle Gustavo Mejía No. 119 B., Santo Domingo, Dominican Republic; e-mail: hispanioland@gmail.com.

***ANOLIS SAGREI* (Brown Anole)**. MÉXICO: VERACRUZ: Municipality of Alvarado: Mandinga (19.019603°N, 96.085397°W; WGS 84), near sea level. 11 October 2012. César Toscano Flores. Verified by Adrian Nieto Montes de Oca. Museo de Zoología Alfonso L. Herrera de la Facultad de Ciencias de la Universidad Nacional Autónoma de México, Mexico City (MZFC 27327). First record for the municipality and a range extension of 100 km N from the nearest known locality at Catemaco, Municipality of San Andrés Tuxtla, Veracruz (Benítes 1997. *In* González Soriano et al. [eds.], Historia Natural de los Tuxtlas, pp. 495–500. Instituto de Biología, UNAM, CONABIO e Instituto de Ecología, UNAM, México, D.F.). The lizard was found at 1000 h on a mangrove tree, ca. 40 cm above ground. The specimen was collected under permit # FAUT-0093 issued by SEMARNAT to Adrian Nieto Montes de Oca.

CÉSAR TOSCANO-FLORES (e-mail: bio.toscanounam@gmail.com) and **RAFAEL ALEJANDRO CALZADA-ARCINIEGA**, Laboratorio de Herpetología, Facultad de Estudios Superiores Iztacala, Universidad Nacional Autónoma de México, Tlalnepantla, Estado de México 54090, México (e-mail: ralejandrocalzada89@gmail.com).

***ANOLIS SAGREI* (Brown Anole)**. USA: FLORIDA: Levy Co: Seahorse Key, hydric hammock adjacent to beach (29.100580°N, 83.061000°W; WGS 84). 30 June 2014 and subsequent dates (below). Coleman M. Sheehy III, Matthew T. Fedler, Tyler A. Gilbert, and Margarita Hernandez. Verified by Kenneth L. Krysko. Florida

Museum of Natural History (UF 174848–904). First observation and documentation of *Anolis sagrei* on Seahorse Key (Krysko et al. 2011. Atlas of Amphibians and Reptiles in Florida. Final report, Florida Fish and Wildlife Conservation Commission, Tallahassee, Florida. 524 pp.).

Seahorse Key is a 64-ha island within the Cedar Keys National Wildlife Refuge (CKNWR). The CKNWR is a group of 13 islands in Florida's Big Bend region, located south of the Suwannee River outflow in the Gulf of Mexico. Seahorse Key is approximately 3 km from Cedar Key, the nearest bridge-connected landmass, and 2 km from the nearest island among the group comprising the CKNWR. During multiple trips between 30 June and 12 December 2014, 57 *A. sagrei* specimens representing both sexes and all age classes were collected within a small area of hydric hammock, known locally as East Cove, at the far east of the island. The *A. sagrei* population on Seahorse Key is located adjacent to a beach called Sandy Point, which is commonly visited by people in boats from nearby Cedar Key. Although *A. sagrei* could have floated or rafted to Seahorse Key from Cedar Key (Schoener and Schoener 1984. Oecologia 63:289–294), we consider this scenario unlikely based on slow water currents in the region and the high risk of predation. Instead, we consider incidental boat transport to be the most parsimonious pathway for this introduction. *Anolis sagrei* was not known from Seahorse Key or adjacent islands during the studies of Charles Wharton (1958. The Ecology of the Cottonmouths *Agkistrodon piscivorus piscivorus* Lacépède of Sea Horse Key, Florida. PhD Dissertation, University of Florida, Gainesville, Florida). Furthermore, CMS and colleagues did not encounter this species on Seahorse Key from 2001–2014 despite conducting herpetological research on the island. The introduced population of *A. sagrei* appears to be restricted to a small area on Seahorse Key at present. Efforts are underway to eradicate this introduced lizard before it disperses to the rest of the island.

COLEMAN M. SHEEHY III (e-mail: coleman3@ufl.edu), **MATTHEW T. FEDLER** (e-mail: asp1177@yahoo.com), **TYLER A. GILBERT** (e-mail: tgilbert0429@ufl.edu), **MARGARITA HERNANDEZ** (e-mail: maggiehern@ufl.edu), and **BENJAMIN K. ATKINSON**, Department of Wildlife Ecology and Conservation and Seahorse Key Marine Laboratory, University of Florida, Gainesville, Florida 32611-0430, USA (e-mail: bka@ufl.edu).

***ANOLIS TIGRINUS* (Tiger Anole)**. VENEZUELA: SUCRE: Municipality of Mariño: Península de Paria, trail between Roma and Cerro Humo (10.694265°N, 62.632466°W; WGS 84), 890 m elev. 31 August 2014. C. Astudillo. Verified by María del Rosario Castañeda. Museo de Biología, Universidad del Zulia, Maracaibo, Venezuela (MBLUZ 1290). Adult female collected after a heavy rain within a patch of intervened cloud forest. *Anolis tigrinus* is endemic to northern Venezuelan and occurs in the states of Anzoategui, Aragua, Falcón, Miranda, Vargas, and Yaracuy, and Distrito Capital (central coastal range and Lara-Falcón hill system), and Sucre state (eastern coastal range). It is found in humid premontane and montane forests between 650 and 2000 m (Ugueto et al. 2009. Carib. J. Sci. 45:31–51). In Sucre, the species was known only from a single specimen from San Rafael, near Cumanacoa, in the lower elevations of the Turimiquire Massif, but has not previously been recorded from adjacent Serranía de Paria, a mountainous chain in northeastern Venezuela (Ugueto et al. 2009, *op. cit.*). This record represents the easternmost distribution and the first mention of the species for Península de Paria, expanding its range extension ca. 150 km NE (airline) of San Rafael, the formerly easternmost record. Also this finding supports a past connection between the montane forest from the Central Coastal Range and Serranía de Paria. The distribution of the frog *Strabomantis biporcatus* (Manzanilla et al. 1996. Herpetol. Rev. 27:29; Barrio-Amorós and Kaiser 2008. Salamandra 44:248254) and the birds *Pipreola formosa* and *Aulacorhyncus sulcatus* (Hilty 2003. Birds of Venezuela. Princeton University Press. Princeton, New Jersey. 776 pp.) also supports such connection.

GILSON A. RIVAS, Museo de Biología, Facultad Experimental de Ciencias, Universidad del Zulia, apartado postal 526, Maracaibo 4011, Venezuela (e-mail: anolis30@hotmail.com); **MAYKE DE FREITAS**, Fundación Proyecto Paria, Calle Rivero, Casa # 50, Río Caribe 6164. Sucre, Venezuela (e-mail: msantos@proyectoparia.org).

***DRACO MINDANENSIS* (Mindanao Flying Lizard)**. PHILIPPINES: SAMAR ISLAND: EASTERN SAMAR PROVINCE: Municipality of Taft: Barangay San Rafael (11.953°N, 125.84893°E; WGS 84) 140 m elev. 22 October 2007. Cameron D. Siler and Jason B. Fernandez. Verified by Jimmy A. McGuire. University of Kansas Biodiversity Institute Herpetology Collections (KU 310847). WESTERN SAMAR PROVINCE: Municipality of San Jose de Buan: Mt. Huraw (12.05262°N, 125.03429°E; WGS 84; 209 m elev. 6 July 2014. Cameron D. Siler, Kerry A. Cobb, Dyanne Realubit, Joseph Brown, Nick Huron, Vicente Yngente, and Marvic Yngente. Verified by Jimmy A. McGuire. KU 337396. First vouchered island records, extending the known range a minimum of ca. 162 km NE of nearest known locality represented by catalogued museum specimens of Mahaplag, Leyte Sur Province, Leyte Island (McGuire and Alcala 2000. Herpetol. Monogr. 14:81–138).

Although this Philippine endemic species has been recognized to occur on Samar Island since 1994, the published report referenced a non-vouchered specimen from a private collection (Gaulke 1994. Hamadryad 19:1–10), and a comprehensive literature review returned no published records of vouchered specimens examined from this island (McGuire and Alcala 2000, op. cit.; McGuire and Kiew 2001. Biol. J. Linn. Soc. 72:203–229). To the best of our knowledge, the two voucher specimens reported here represent the only published museum records of populations of this species on Samar Island. Both specimens were collected sleeping at night on low-lying branches of trees in the middle of secondary-growth forest. Fieldwork was supported by NSF DEB 0743491 and NSF EF-0334952 to RMB, and NSF DEB 0804115 and NSF IOS 1353683 to CDS.

***HEMIDACTYLUS TURCICUS* (Mediterranean Gecko).** USA: OKLAHOMA: Tulsa Co.: City of Tulsa (36.115422°N, 95.982848°W; WGS 84). 15 May 2013. John G. Phillips and Stacey L. Hannebaum. Verified by Stan E. Trauth. Arkansas State University Museum of Zoology (ASUMZ 33349, photographic voucher). New county record (Oklahoma Biological Survey, Distribution of Oklahoma Amphibians and Reptiles by Recorded Sightings [DOKARRS], http://www.biosurvey.ou.edu/dokarrs_srch.html). Known from scattered localities across the state (Sievert and Sievert 2011. A Field Guide to Oklahoma's Amphibians and Reptiles, 3rd ed. Oklahoma Deptment of Wildlife Conservation, Oklahoma City, Oklahoma. 211 pp.). Specimen was found in an apartment complex, which is no longer present at the location. Further investigation revealed at least 30 more individuals of varying sizes. Since 15 May 2013, *H. turcicus* has been seen and heard at other locations within the city of Tulsa.

JOHN G. PHILLIPS (e-mail: john-phillips@utulsa.edu) and **STACEY L. HANNEBAUM**, Department of Biological Sciences, University of Tulsa, Tulsa, Oklahoma 74104, USA.

***IGUANA IGUANA* (Common Green Iguana).** MÉXICO: BAJA CALIFORNIA SUR: Municipality of Los Cabos: Los Cabos, Estero San José del Cabo (23.050305°N, 109.688080°W; WGS 84), 4 m elev. 22 June 2014. V. H. Luja. Verified by Luis Canseco Márquez. Amphibian and Reptile Diversity Research Center (UTADC 8198, photographic voucher). First state record for this introduced species (Grismer 2002. Amphibians and Reptiles of Baja California: including its Pacific Islands and the Islands in the Sea of Cortez. University of California Press, Berkeley, California. 399 pp.). An adult male was observed perched on a tree in the Estero San Jose Oasis; the lizard subsequently jumped into the water and swam into aquatic vegetation.

VÍCTOR H. LUJA, Unidad Académica de Turismo, Coordinación y Posgrado, Ciudad de la Cultura Amado Nervo s/n, C. P. 63155 Tepic, Nayarit, México, e-mail: lujastro@yahoo.com.

***LIOLAEMUS NIGROMACULATUS* (Many-spotted Tree Iguana).** CHILE: ANTOFAGASTA: Las Terrazas Beach, Paposo (25.1400°S, 70.4613°W; WGS 84). 1 February 2015. Marcos Ferrú González. Verified by Jaime Troncoso-Palacios. Colección Patricio Sánchez Reyes de la Pontificia Universidad Católica de Chile**,** Santiago, Región Metropolitana (SSUC 642, 643). The specimens were captured under rocks on sandy area with shrub vegetation (*Nolana* sp.). The species is known only from Caldera to Huasco in the Atacama Region (Troncoso and Garín 2013. ZooKeys 294:37–56). This new record extends the known range 230 km (airline) N of Caldera, the closest known locality. Specimens collected under an approved SAG permit (Resolución Exenta 9487/2014).

MARGARITA RUIZ DE GAMBOA ASTROZA, Programa de Doctorado en Sistemática y Biodiversidad, Departamento de Zoología, Universidad de Concepción, Barrio Universitario s/n, Concepción, Chile (e-mail: mruizdg@gmail.com); **MARCOS FERRÚ GONZALEZ**, Programa de Magister en Ciencias mención Zoología, Departamento de Zoología, Universidad de Concepción, Luis Acevedo 456, Chiguayante, Chile.

***PHRYNOSOMA CORNUTUM* (Texas Horned Lizard).** USA: TEXAS: Yoakum Co.: The Nature Conservancy's Yoakum Dunes Preserve (33.375015°N, 102.626817°W, NAD 83). 1 August 2013. Texas Natural History Collections (TNHC 92828, 92829; photographic vouchers). A third individual was observed at this locality on 8 September 2013 (TNHC 92831, photographic voucher). The Nature Conservancy's Yoakum Dunes Preserve (33.368384°N, 102.623166°W, NAD 83). 1 September 2013. TNHC 92830 (photographic voucher). New county record filling a distributional hiatus between all surrounding Texas counties and eastern New Mexico (Dixon 2013. Amphibians and Reptiles of Texas: with Keys, Taxonomic Synopses, Bibliography, and Distribution Maps. Texas A&M University Press, College Station, Texas. 447 pp.). Both specimens were found by Jacob Kemmer and verified by Travis J. LaDuc.

We thank The Nature Conservancy of Texas for access to the property and project support. Specimens were collected under a Texas Parks and Wildlife Department Scientific Collecting Permit (SPR-0300-087) issued to ACK.

JACOB A. KEMMER (e-mail: jacob.kemmer92@outlook.com) and **ANDREW C. KASNER**, School of Mathematics and Sciences, Wayland Baptist University, 1900 W. 7th, CMB 1285, Plainview, Texas 79072, USA (e-mail: kasnera@wbu.edu).

***PLESTIODON EGREGIUS SIMILIS* (Northern Mole Skink)**. USA: FLORIDA: Hamilton Co: Suwannee Ridge Mitigation Park Wildlife and Environmental Area (30.44366°N, 83.04613°W; WGS 84). 8 May 2014. Kevin M. Enge. Verified by Kenneth L. Krysko. Florida Museum of Natural History (UF 173275, photographic voucher). First record for the county (Krysko et al. 2011. Atlas of Amphibians and Reptiles in Florida. Final report, Florida Fish and Wildlife Conservation Commission, Tallahassee, Florida. 524 pp.). Adult male trapped by a drift fence installed in sandhill habitat.

KEVIN M. ENGE (e-mail: kevin.enge@myfwc.com), **CODY D. GODWIN,** and **JONATHAN D. MAYS**, Florida Fish and Wildlife Conservation Commission, 1105 S.W. Williston Road, Gainesville, Florida 32601, USA.

***SCELOPORUS CONSOBRINUS* (Prairie Lizard)**. USA: TEXAS: Robertson Co.: Approximately 11 km E of Hearne (30.872176°N, 96.483453°W; WGS 84), 135 m elev. 7 April 2014. Zachary C. Adcock, Andrew R. MacLaren, Shawn F. McCracken, and Michael R. J. Forstner. Verified by Toby J. Hibbitts. Biodiversity Research and Teaching Collections (TCWC 100267). New county record (Dixon 2013. Amphibians and Reptiles of Texas: with Keys, Taxonomic Synopses, Bibliography, and Distribution Maps. Texas A&M University Press, College Station, Texas. 447 pp.). This record fills a distributional gap within the surrounding Milam, Falls, Limestone, Leon, Madison, Brazos, and Burleson counties. Unreported records of *S. consobrinus* from Robertson Co. exist at the Biodiversity Research and Teaching Collections, but this specimen represents the first confirmed and published *S. consobrinus* record from the county. The nearest (previously unreported) record is 7 km SE (TCWC 61934). Adult male specimen (58.2 mm SVL; 127.0 mm TL) collected during a visual encounter survey. Numerous additional individuals (not vouchered) observed during visual encounter, bucket trap, and artificial cover object surveys on the property. Property is located on the Carrizo Sands outcrop in Post Oak savannah habitat. Specimen collected under Scientific Collecting Permit (SPR-0102-191) issued to MRJF by Texas Parks and Wildlife Department.

ZACHARY C. ADCOCK (e-mail: zca3@txstate.edu), **ANDREW R. MACLAREN**, **SHAWN F. McCRACKEN**, and **MICHAEL R. J. FORSTNER**, Department of Biology, Texas State University, 601 University Drive, San Marcos, Texas 78666, USA.

SQUAMATA — SNAKES

***BOIGA NIGRICEPS* (Black-headed Cat Snake)**. INDONESIA: BALI: Tabanan Regency: West Selemadeg, vicinity of Selabih (8.457485°S, 114.918449°E; WGS 84). 19 January 2015. J. Vink. Verified by Jason Luke. Lee Kong Chian Natural History Museum, National University of Singapore (ZRC [IMG] 2.245a–d, photographic voucher). Found on thin branches of a live tree, 5 m up on tree trunk, in a residual rainforest behind houses. First record for Bali (McKay 2006. A Field Guide to the Amphibians and Reptiles of Bali. Krieger Publishing Co., Malabar, Florida. 138 pp.). Indonesian populations are known from Kalimantan (Borneo), Sumatra, and Java (Stuebing et al. 2014. A Field Guide to the Snakes of Borneo, 2nd ed. Natural History Publications [Borneo] Sdn Bhd., Kota Kinabalu, Malaysia. 310 pp.), and its distribution includes southern Thailand, and Peninsular and East Malaysia (Das 2010. A Field Guide to the Reptiles of South-east Asia. New Holland Publishers [UK] Ltd., London. 376 pp.; Das 2012. A Naturalist's Guide to the Snakes of South-east Asia. John Beaufoy Publishing, London. 160 pp.).

***CEMOPHORA COCCINEA COPEI* (Northern Scarletsnake)**. USA: FLORIDA: Hamilton Co: Suwannee Ridge Mitigation Park Wildlife and Environmental Area (30.44366°N, 83.04613°W; WGS 84). 3 June 2014. Jonathan D. Mays. Verified by Kenneth L. Krysko. Florida Museum of Natural History (UF 173271, photographic voucher). First county record (Krysko et al. 2011. Atlas of Amphibians and Reptiles in Florida. Final report, Florida Fish and Wildlife Conservation Commission, Tallahassee. 524 pp.). Adult male trapped by a drift fence installed in sandhill habitat.

JONATHAN D. MAYS (e-mail: jonathan.mays@myfwc.com), **KEVIN M. ENGE**, and **CODY D. GODWIN**, Florida Fish and Wildlife Conservation Commission, 1105 S.W. Williston Road, Gainesville, Florida 32601, USA.

***COELOGNATHUS ERYTHRURUS PSEPHENOURUS* (Philippine Gray-tailed Ratsnake)**. PHILIPPINES: TABLAS ISLAND: Romblon Province: Municipality of Odiongan, Barangay Poctoy (12.410418°N, 121.990697°E, WGS 84) 8 m elev. 31 October 2014. Ernest Kurt Tan. Verified by Rafe M. Brown. Photographic voucher, Lee Kong Chian Natural History Museum, National University of Singapore (ZRC[IMG] 2.244a–c). This specimen represents the first record for Tablas Island and Romblon Province (Siler et al. 2012. Check List 8[3]:443–462) and was collected DOR. *Coelognathus erythrurus psephenourus* is an endemic taxon that has previously been recorded on Cebu, Guimaras, Masbate, Negros, and Panay (Leviton 1977. Philippines J. Sci. 106:99–128; Gaulke and Altenbach 1994. Herpetozoa 7:63–66).

***COLUBER CONSTRICTOR* (North American Racer)**. USA: NEBRASKA: Cedar Co.: Bow Creek Recreation Area, Missouri National Recreational River (42.77806°N, 97.14611°W; WGS 84). 25 June 2014. Spencer R. Siddons. Verified by Jessa L. Watters. Sam Noble Oklahoma Museum of Natural History (OMNH 44149). New county record (Ballinger et al. 2010. Amphibians and Reptiles of Nebraska. Rusty Lizard Press, Oro Valley, Arizona. 400 pp.; Fogell 2010. A Field Guide to the Amphibians and Reptiles of Nebraska. University of Nebraska-Lincoln, Lincoln, Nebraska. 158 pp.). Previous records exist to the west in Knox Co. and across the Missouri River to the north in Clay Co., South Dakota (Ballinger et al. 2000. Trans. Nebraska Acad. Sci. 26:29–46; Ballinger et al. 2010, *op. cit.*; Fogell 2010, *op. cit.*). The nearest known specimen is from ca. 18 km to the east and across the Missouri River in Vermillion, Clay Co., South Dakota (University of Nebraska State Museum [UNSM] 16108). This specimen fills part of a large gap in the known distribution of this species in northeastern Nebraska. Adult female (872 mm SVL; 218 mm tail length; 225.51 g) collected along trail approximately 150 m NE of parking area and

had recently consumed a large vole (*Microtus* sp.). Specimen collected under a Nebraska Game and Parks Commission Scientific and Educational Collecting Permit (#472) issued to DRD.

SPENCER R. SIDDONS (e-mail: spencer.siddons@usd.edu), **ALICE R. MILLIKIN** (e-mail: alicemillikin@gmail.com), and **DREW R. DAVIS**, Department of Biology, University of South Dakota, 414 East Clark Street, Vermillion, South Dakota 57069, USA (e-mail: drew.davis@usd.edu).

***COLUBER CONSTRICTOR* (North American Racer)**. USA: TEXAS: Floyd Co.: 14.37 rd km E of Junction Hwy 70 and FM 1958 (33.97897°N,101.1702583333°W; WGS 84). 7 November 2014. Toby J. Hibbitts and Connor S. Adams. Verified by James R. Dixon. Biodiversity Research and Teaching Collections (TCWC 100293). New county record (Dixon 2013. Amphibians and Reptiles of Texas: with Keys, Taxonomic Synopses, Bibliography, and Distribution Maps. Texas A&M University Press, College Station, Texas. 447 pp.). Known from neighboring Motley and Swisher counties in Texas (Dixon 2013, *op. cit.*). Specimen collected under a Texas Parks and Wildlife Scientific Collecting Permit (SPR-0506-662) issued to TJH.

TOBY J. HIBBITTS (e-mail: thibbitts@tamu.edu) and **CONNOR S. ADAMS**, Texas Cooperative Wildlife Collections, Department of Wildlife and Fisheries Sciences, Texas A&M University, 2258 Tamu, College Station, Texas 77843-2258, USA.

***CROTALUS ATROX* (Western Diamond-backed Rattlesnake)**. USA: TEXAS: Gaines Co.: 1.76 rd km S of Co Rd 426 on Norman Rd (32.523288°N, 102.55939°W; WGS 84). 1 August 2012. Connor S. Adams. Verified by James R. Dixon. Biodiversity Research and Teaching Collections (TCWC 96939). New county record (Dixon 2013. Amphibians and Reptiles of Texas: with Keys, Taxonomic Synopses, Bibliography, and Distribution Maps. Texas A&M University Press, College Station, Texas. 447 pp.). Known from neighboring Andrews, Dawson, Martin, and Terry counties in Texas and from Lea and Roosevelt counties, New Mexico. (Degenhart et al. 1996. Amphibians and Reptiles of New Mexico. University of New Mexico Press, Albuquerque, New Mexico. 431 pp.; Dixon 2013, *op. cit.*).

This specimen was collected during research on *Sceloporus arenicolus* with funding from Texas Comptrollers Office and under a Texas Parks and Wildlife Scientific Collecting Permit (SPR-0506-662) issued to TJH.

TOBY J. HIBBITTS (e-mail: thibbitts@tamu.edu) and **CONNOR S. ADAMS**, Texas Cooperative Wildlife Collections, Department of Wildlife and Fisheries Sciences, Texas A&M University, 2258 Tamu, College Station, Texas 77843-2258, USA.

***CROTALUS BASILISCUS* (Mexican West Coast Rattlesnake)**. MÉXICO: AGUASCALIENTES: Municipality of Calvillo: 0.5 km SE El Terrero del Refugio (21.863307°N, 102.839317°W; WGS 84), 2278 m elev. 28 August 2013. Rubén A. Carbajal Márquez and Eric A. Rivas Mercado. Verified by J. A. Campbell. University of Texas at Arlington, Department of Biology, Arlington, Texas (UTADC 8484–8486, photographic voucher). First record for Aguascalientes, with the closest known locality being 80 km SSW from 2.25 km N of Santa Rosa, Moyahua de Estrada, Zacatecas (Ahumada-Carrillo et al. 2011. Herpetol. Rev. 42:397–398). The specimen was found DOR in a tropical deciduous forest and oak forest ecotone.

RUBÉN A. CARBAJAL-MÁRQUEZ, Centro de Investigaciones Biológicas del Noroeste, Instituto Politécnico Nacional No. 195, Col. Playa Palo de Santa Rita Sur, C. ***CROTALUS TOTONACUS* (Totonacan Rattlesnake)**. MÉXICO: HIDALGO: Municipality of Nicolas Flores: near El Molino (20.882302°N, 99.149187°W; WGS 84), 1715 m elev. 3 October 2013. Jorge Iván Ángeles Escudero and Josefína Ramos Frías. Verified by Norma Manríquez-Morán. Herpetological Photographic Collection, Centro de Investigaciones Biológicas, Universidad Autónoma del Estado de Hidalgo (CH-CIB 05). First record for the municipality, extending the range within Hidalgo ca.14.25 km SW from the closest known locality at Jacala de Ledezma, Municipality of Jacala de Ledezma (Valencia-Hernández et al. 2007. Acta Zool. Mex. 23:3). The snake was found in pine forest. Municipality of Pacula: near Adjuntas (20.948787ºN, 99.236706ºW; WGS 84), 1925 m elev. 12 October 2012. Josefína Ramos Frías and Melany Aguilar López. Verified by Norma Manríquez-Morán. CH-CIB 06-07. First record for the municipality, extending the range within Hidalgo 7.91 km SE from the closest known locality at Jacala de Ledezma, Municipality of Jacala de Ledezma (Valencia-Hernández et al. 2007, *op. cit.*). It is also the highest elevational record for the species; *C. totonacus* was known previously to occupy elevations up to 1800 m (Valencia-Hernández et al. 2007, *op. cit.*). The snake was found during midday on the ground in oak forest containing secondary vegetation.

JOSEFINA RAMOS FRÍAS (e-mail: tia_chepis@hotmail.com) and **LEONARDO FERNÁNDEZ-BADILLO**, Centro de Investigaciones Biológicas (CIB), Universidad Autónoma del Estado de Hidalgo, A. ***HETERODON SIMUS* (Southern Hog-nosed Snake)**. USA: FLORIDA: Hamilton Co.: County Road 249 (30.45916°N, 83.06802°W; WGS 84). 16 October 2014. Jonathan D. Mays. Verified by Kenneth L. Krysko. Florida Museum of Natural History (UF 174564). First

record for the county (Krysko et al. 2011. Atlas of Amphibians and Reptiles in Florida. Final report, Florida Fish and Wildlife Conservation Commission, Tallahassee, Florida. 524 pp.). Adult male found DOR.

JONATHAN D. MAYS, Florida Fish and Wildlife Conservation Commission, 1105 S.W. Williston Road, Gainesville, Florida 32601, USA, e-mail: jonathan.mays@myfwc.com.

***INDOTYPHLOPS BRAMINUS* (Brahminy Blindsnake; Culebra Ciega)**. HONDURAS: ATLÁNTIDA: Salada Barro, Cuero y Salado Wildlife Refuge (15.76668°N, 86.983606°W; WGS 84), 5 m elev. 5 December 2012. James R. McCranie and Leonardo Valdés Orellana. Verified by José Rosado. Museum of Comparative Zoology (MCZ R-191073, 191076–84). First records of this introduced species from Atlántida, with the nearest known mainland locality located ca. 120 km SW in San Pedro Sula, Cortés (McCranie et al. 2014. Herpetol. Rev. 45:285). The species has also been reported from Isla de Utila, Islas de la Bahía, Honduras (Vesely and Köhler 2009. Herpetol. Rev. 40:116). The snakes were below root systems of dead coconut palm stumps. Other uncollected individuals of *I. braminus* were also observed at the site, which indicates a well-established breeding population. We thank Lic Anuar for providing lodging and field assistance during our visit to Salada Barro. This specimen was collected under approved permits (DICTAMEN-ASG-ICF-135-2012, RESOLUCION-DE-MP-102-2012).

Dixon. Biodiversity Research and Teaching Collections (TCWC 97154). New county record (Dixon 2013. Amphibians and Reptiles of Texas: with Keys, Taxonomic Synopses, Bibliography, and Distribution Maps. Texas A&M University Press, College Station, Texas. 447 pp.). Known from neighboring Midland Co. in Texas and from Lea Co., New Mexico (Degenhardt et al. 1996. Amphibians and Reptiles of New Mexico. University of New Mexico Press, Albuquerque, New Mexico. 431 pp.; Dixon 2013, *op. cit.*).

This specimen was collected during research on *Sceloporus arenicolus* with funding from Texas Comptrollers Office and under a Texas Parks and Wildlife Scientific Collecting Permit (SPR-0506-662) issued to TJH.

TOBY J. HIBBITTS and **CONNOR S. ADAMS** Texas Cooperative Wildlife Collections, Department of Wildlife and Fisheries Sciences, Texas A&M University, 2258 Tamu, College Station, Texas 77843-2258, USA, e-mail: thibbitts@tamu.edu.

***TANTILLA VERMIFORMIS* (Hallowell's Centipede Snake)**. GUATEMALA: ZACAPA: Municipality of Cabañas: Reserva Natural para la Conservación del Heloderma y el Bosque Seco, 4 km W of El Arenal (14.862970°N, 89.788197°W; WGS 84), 590 m elev. 2 May 2014. Daniel Ariano-Sánchez. Verified by Jonathan Campbell. Colecciones Biológicas de la Universidad del Valle de Guatemala, Ciudad de Guatemala, Guatemala (UVG 7000). First record for this species from Guatemala, and a range extension of ca. 127 km N from nearest known locality in the vicinity of Sonsonate, El Salvador (Wilson 1999. Smithson. Herpetol. Info. Serv. 122:134; Köhler 2008. Reptiles of Central America, 2nd ed. Herpeton Verlag, Offenbach, Germany. 400 pp.; Wilson and Johnson 2010. *In* Wilson et al. [eds.], Conservation of Mesoamerican Amphibians and Reptiles, pp. 32235. Eagle Mountain Publishing, Eagle Mountain, Utah). This record joins a list of other recent range extensions that came from Reserva Natural para la Conservación del Heloderma y el Bosque Seco supporting its relevance for conservation of the dry forest herpetofauna of Guatemala (Ariano-Sánchez et al. 2010. Herpetol. Rev. 41:107; Ariano-Sánchez and Dix 2010. Herpetol. Rev. 41:505). The adult female was found

crawling across a sandy clearing at 2300 h within seasonally dry tropical forest. I thank the students of General Ecology course at Universidad del Valle de Guatemala who showed me the unregistered trail passing through the forest where the snake was discovered. ZOOTROPIC and CONAP (033/2014) provided permits to conduct scientific research at the reserve.

DANIEL ARIANO-SÁNCHEZ, Departamento de Biología, Universidad del Valle de Guatemala, Ciudad de Guatemala, Guatemala; e-mail: dariano@uvg.edu.gt.

***THAMNOPHIS RADIX* (Plains Gartersnake)**. USA: NEBRASKA: Thomas Co.: NE Hwy 2, ca. 2.2 rd km W jct Spur 86B (41.91366°N, 100.32042°W; WGS 84). 20 October 2014. Drew R. Davis and James W. Stewart. Verified by Travis J. LaDuc. Texas Natural History Collections (TNHC 93510). New county record (Ballinger et al. 2010. Amphibians and Reptiles of Nebraska. Rusty Lizard Press, Oro Valley, Arizona. 400 pp.; Fogell 2010. A Field Guide to the Amphibians and Reptiles of Nebraska. University of Nebraska-Lincoln, Lincoln, Nebraska. 158 pp.). Adult female (574 mm SVL; 151 mm tail length; 92.76 g) collected DOR along highway running along N boundary of the Nebraska National Forest, Bessey District. This species is known from the surrounding counties (Cherry, Blaine, Logan, McPherson) except directly to the west in Hooker County, Nebraska (Ballinger et al. 2010, *op. cit.*; Fogell 2010, *op. cit.*). The nearest known specimen is from ca. 23 km to the NE from northwest Blaine Co., Nebraska (University of Nebraska State Museum [UNSM] 9298). Specimen collected under a Nebraska Game and Parks Commission Scientific and Educational Permit (#472) issued to DRD.

JAMES W. STEWART (e-mail: james.tn.stewart@gmail.com) and **DREW R. DAVIS**, Department of Biology, University of South Dakota, 414 East Clark Street, Vermillion, South Dakota 57069, USA (e-mail: drew.davis@usd.edu).

***TRILEPIDA KOPPESI* (Amaral's Blind Snake)**. BRAZIL: MINAS GERAIS: Municipality of Governador Valadares: São Manoel Island (19.01°S, 42.11°W; SAD 69), 181 m elev. 19–23 December 2008. R. Filogonio and M. A. S. Canelas. Verified by V. Germano. Museu de Ciências Naturais, Pontifícia Universidade Católica de Minas Gerais, Belo Horizonte, Minas Gerais (MCNR 3294–3296). *Trilepida koppesi* is known from Mato Grosso do Sul (Parnaíba and Terenos), Goiás (Mineiros), São Paulo (Mogi-Guaçú, Brotas, Itirapina, and Pirassununga), and Tocantins (Palmas) states (Passos et al. 2006. Amphibia-Reptilia 27:347–357; Pinto and Fernandes 2012. Copeia 2012:37–48). First state record that increases the known distribution ca. 624 km (airline) NE of Mogi-Guaçú, ca. 1100 km E of Mineiros, and is the closest record to the litoral. Permits were issued by Instituto Brasileiro do Meio Ambiente e Recursos Naturais Renováveis (IBAMA) under licenses nº141/2008 NUFAS/MG Process IBAMA nº02015.011675/2007-25, and nº516/2009 NUFAS/MG Process IBAMA nº02015.011675/2007-26.

New Distributional Records of Amphibians and Reptiles from Nayarit, México

The herpetofauna of Nayarit has received less consideration when compared to most other Mexican states (Flores-Villela et al. 2004). To date, 37 species of amphibians (Luja et al. 2014) and 88 of reptiles (Flores-Villela and García-Vázquez 2014) have been documented from the state. Other studies listing species from Nayarit include: Lewis and Johnson (1955), Zweifel (1959, 1960), McDiarmid (1963), McDiarmid et al. (1976), Casas-Andreu (1992), Canseco-Márquez et al. (2007), de la Torre et al. (2010), and Ahumada-Carrillo et al. (2013). In order to contribute further to the knowledge of the herpetofauna of Nayarit, we conducted field surveys in several locations within the state from 2011 to 2014. Herein we present four accounts for species new to Nayarit; five first municipality records, one of which is for a species previously feared to be extinct; and one other significant range extension. All animals were photographed by V. H. Luja, unless otherwise noted. Voucher specimens were placed in the Museo de Zoología "Alfonso L. Herrera," Facultad de Ciencias, Universidad Nacional Autónoma de México, Ciudad de México, México (MZFC), and photographs of specimens not collected are in University of Texas at Arlington Digital Photograph Collection, Arlington, Texas (UTADC). Locality coordinates were taken with a GPS device using map datum WGS84. Common English names follow Liner and Casas-Andreu (2008).

CAUDATA — SALAMANDERS

***AMBYSTOMA ROSACEUM* (Tarahumara Salamander).** Municipality of Del Nayar: La Cascada, 1.4 km SW Santa Teresa. (22.485653°N, 104.772542°W), 2085 m elev. 22 February 2014. V. H. Luja. Verified by L. Canseco-Márquez. UTADC 8102. First municipality record, filling a distribution gap of 245 km between El Salto, Durango (KU 69268), and Sierra de Alica, Nayarit (Canseco-Márquez et al. 2007). The two larvae were found in a stream passing through a mixture of grassland and pine-oak forest. CIG found an adult in the same municipality in 2008; its unique coloration helped confirm identity of the larvae.

ANURA — FROGS

***PLECTROHYLA BISTINCTA* (Mexican Fringe-limbed Treefrog).** Municipality of Xalisco: Rancho La Noria, 9 km W Tepic (21.483444°N, 104.999028°W), 1546 m elev. 19 July 2013. V. H. Luja. Verified by E. Pérez-Ramos. MZFC 28147, 28166–67. First municipality record, filling a distribution gap of 195 km between Santa Teresa, Nayarit (Duellman 2001) and La Estancia, Jalisco (Reyes-Velasco et al. 2012). Seventy eggs, four adults, and dozens of tadpoles were found in an artificial pond in an ecotone between cloud forest and oak forest. A second population was discovered on 27 September 2013 in the same municipality at El Cuarenteño (21.448889°N, 105.0365830°W), 920 m elev., where 25 juveniles were found on coffee plants alongside a stream.

SQUAMATA — LIZARDS

***SCELOPORUS POINSETTII* (Crevice Spiny Lizard).** Municipality of Del Nayar: Cerro Sagrado, 1.3 km NE Santa Teresa (22.5077°N, 104.758419°W), 2205 m elev. 22 February 2014. V. H. Luja. Verified by C. J. Franklin. UTADC 8101, 8103. First state records, which fill a 410-km gap in the known distribution between Rancho Las Margaritas, Durango, and Rincon de Manantlán, Sierra de Manantlán, Jalisco (Webb 2006). The lizards were found in the morning under rock piles in pine-oak forest.

***ELGARIA KINGII* (Madrean Alligator Lizard).** Municipality of Xalisco: Sierra San Juan: El Cuarenteño (21.44889°N, 105.036583°W), 920 m elev. 27 September 2013. V. H. Luja. Verified by L. Canseco-Márquez. UTADC 8104. First municipality record and second for the state, extending the known range ca. 78 km W from the Sierra de Alica (Canseco-Márquez et al. 2007). The lizard was found on leaf litter in a coffee plantation. Municipality of Tepic: Km 7 on the road to Rancho La Noria, Sierra San Juan (21.499956°N, 104.988647°W), 1472 m. elev. 6 December 2013. V. H. Luja. Verified by J. Reyes-Velasco. UTADC 8131. First municipality record; the closest known locality is at Sierra de Alica, which lies 75 km to the east. The lizard was found DOR in an ecotone between pine-oak and tropical deciduous forest.

SQUAMATA — SNAKES

***CROTALUS CAMPBELLI* (Campbell's Dusky Rattlesnake).** Municipality of Xalisco: Sierra San Juan (21.4450°N, 104.980514°W), 2010 m elev. 6 October 2013. Victor H. Luja. Verified by Jacobo Reyes-Velasco. UTADC 8108. First record for Nayarit, extending the known range 100 km NNW from Lago de Juanacatlán, Municipality of Mascota, Jalisco (Bryson et al. 2014). The snake was found during the day in a rocky pine-oak forest containing an abundance of ferns.

***GEOPHIS DUGESI* (Dugès' Earth Snake).** Municipality of Tepic: Sierra San Juan (21.497067°N, 104.988494°W), 1522 m elev. 24 July 2013. V. H. Luja. Verified by E. Pérez-Ramos. MZFC 28171. First record for Nayarit, extending the known range ca. 86 km NNW of an unpublished record at 22.4 km NW of Mascota, Jalisco (KU 110100) and ca. 240 km SSE from 19.2 km NE of Santa Lucia, Sinaloa, which was tentatively assigned to this species by Hardy and McDiarmid (1969) and validated by Webb (1976).

PHOTO BY CHRISTOPH I. GRÜNWALD

FIG. 1. Adult *Thamnophis rossmani* observed 3 km S of Pantanal, Xalisco, Nayarit, Mexico on 10 July 2011. This is the first photograph of a live specimen, and first reported observation since 1969.

The snake was found in a rocky shaded area in an ecotone between pine forest and tropical deciduous forest.

***RHADINAEA HESPERIA* (Western Graceful Brown Snake).** MUNICIPALITY OF XALISCO: Rancho La Noria, Sierra San Juan (21.497067°N, 104.995464°W), 1607 m elev. 15 September 2012. V. H. Luja. Verified by J. Reyes-Velasco. UTADC 8105. First municipality record, and westernmost record in Nayarit, extending the known range in the state ca. 80 km W of road from Huajimic to Guadalupe Ocotlán in the Sierra de Alica (Canseco-Márquez et al. 2007). There are two other unpublished records for Nayarit, one from the southeastern slope of a high ridge north of the village of Mesa del Nayar, on road to Santa Teresa (CAS 169688), and another from 22.3 mi (35.59 km) SE of Tepic along Mex. Hwy 15 (LACM 103653). The Rancho La Noria snake was found in the morning moving on leaf litter in a pine-oak forest.

***RHADINAEA TAENIATA* (Pine-Oak Snake).** MUNICIPALITY OF TEPIC: Road to Rancho La Noria, Sierra San Juan (21.497833°N, 104.989142°W), 1500 m elev. 6 December 2013. V. H. Luja. Verified by I. Ahumada-Carrillo. UTADC 8106. First record for Nayarit and northernmost record for the species, representing a range extension of ca. 222 km NNW from La Joya, Sierra Manantlán, Jalisco (Orozco-Uribe 2009). The snake was found DOR in pine-oak forest.

***STORERIA STORERIOIDES* (Mexican Brown Snake).** MUNICIPALITY OF XALISCO: Sierra San Juan (21.454628°N, 104.997947°W), 1479 m elev. 6 October 2013. V. H. Luja. Verified by I. Ahumada-Carrillo. UTADC 8107. First published record for Nayarit, filling a distributional gap of ca. 380 km in its known range between 19.2 km NE of Santa Lucia, Sinaloa (Hardy and McDiarmid 1969), and 14.48 km E of Talpa de Allende, Jalisco (Ernst 2008). There are two unpublished records from Nayarit, one from near Cueva de Las Guacamayas, ca. 10 km E of Lagunitas (UAZ 26389), which is located east of Huajicori, and the other is from the crest of a high ridge north of the village of Mesa del Nayar, on road to Santa Teresa (CAS 169689); the record reported herein lies ca. 144 km S and 92 km SSW, respectively, of those localities. The snake was found under a rock in pine forest.

***THAMNOPHIS ROSSMANI* (Rossman's Garter Snake).** MUNICIPALITY OF XALISCO: 3 km S of Pantanal. (21.409086°N, 104.409086°W), 921 m elev. 10 July 2011. C. I. Grünwald, J. M. Jones, and L. Gallegos-Roman. Verified by Douglas Rossman. UTADC 8122 (Fig. 1). First record for the municipality and first rediscovery since 1969 (Conant 2000) for this imperiled species that apparently is restricted to the San Cayetano Valley of southeastern Nayarit. The snake was found under a piece of trash in a marshy area after searching about 20 minutes; the habitat has been heavily altered by anthropogenic activity.

Acknowledgments.—We thank Jason M. Jones and Luis Gallegos-Roman for their help in the field. We also recognize Douglas Rossman for his extensive work on Mexican *Thamnophis*, and his unfaltering readiness to tackle any identification problem that presented itself over our years of fieldwork.

Artist Amy Gross

The Isla San Marcos Night Snake (*Hypsiglena marcosensis*) is a rarely observed island endemic known only from Isla San Marcos in the Gulf of California. **Amy H. Gross** painted this species for the San Diego Natural History Museum's (SDNHM) *Amphibian and Reptile Atlas of Peninsular California*. The SDNHM is both a museum and a prolific research facility with working scientists. These scientists work in the Biodiversity Research Center of the Californias (BRCC) through which they conduct field research in southern California and throughout Baja California, Mexico, among other regions. The *Amphibian and Reptile Atlas* is a joint project between scientists at the SDNHM and institutions in Baja California, Mexico, funded by the Institute for Museum and Library Services. It is a growing atlas that uses data collected by museum scientists and the contributing public to better understand the biodiversity of the southern California and Baja California region: http://herpatlas.sdnhm.org/.

Amy helped contribute to the atlas by creating artistic renderings of rare species that either lacked accurate photographs or have never been photographed at all. She digitally painted the Isla San Marcos Night Snake in Adobe Photoshop. The painting process involved using photo references of closely related species and working with descriptions of the Isla San Marcos Night Snake in order to paint a true representation of the species.

Amy initially studied Wildlife Studies at Humboldt State University, but then switched majors to pursue an Art degree. After studying Fine Art Reproduction at a forgery studio in Italy, Amy returned to San Diego and decided to combine her passions in order to become a Scientific Illustrator. She's currently a freelance illustrator and continues to contribute paintings to the SDNHM Reptile and Amphibian Atlas. She also works in the museum's education department, teaching children and adults alike about the importance of our natural world.

Amy can be contacted about commissions through her website: www.amyhgross.com.

NATURAL HISTORY NOTES

CAUDATA — SALAMANDERS

***DESMOGNATHUS FUSCUS FUSCUS* (Northern Dusky Salamander). LARVAL ATTENDANCE.** *Desmognathus fuscus* is a semi-aquatic plethodontid salamander that oviposits in or near water, where aquatic larvae develop. Attendance of eggs by females is well-documented as a vital behavior for successful reproduction in this species; clutches are rarely abandoned, as this frequently results in complete failure (Hom 1987. Copeia 1987:768–777). Female attendance of eggs is expected in plethodontid species that can oviposit terrestrially (Wells. 2007. The Ecology and Behavior of Amphibians. University of Chicago Press, Chicago, Illinois. 1148 pp.). When offspring are direct-developing, such as in *Plethodon cinereus* (Eastern Red-backed Salamander), females have been observed remaining in nest sites with juveniles for weeks (Petranka 1998. Salamanders of the United States and Canada. Smithsonian Institution Press, Washington and London. 587 pp.). In species with aquatic larvae like *D. fuscus*, females may remain in terrestrial nests for a few days after clutches hatch, before the larvae move to water (Juterbock 1987. Herpetologica 43:361–368; Wells 2007, *op. cit*). This note expands the time period and role of attendance to aquatic larvae in Plethodontids that can oviposit terrestrially, with further observations of female *D. fuscus* and their larvae remaining in nest sites.

Two nests of *D. fuscus* were observed along the dry headwaters of Bower's Spring, Worcester Co., Massachusetts, USA (42.4673°N, 71.6051°W, WGS84). The first nest was found on 4 October 2014, as the clutch was hatching, under a small moss mat overhanging the damp run bed. From 7–9 October 2014, the female and at least 10 larvae were visible in this nest each day, generally in close contact. One larva was unearthed in the mud below the nest on 9 October 2014. On 10 October 2014 the female was barely responsive and dry to the touch; 8 larvae remained in the nest, but appeared to be dispersing rather than grouped as previously observed. A second nest was found slightly downstream on 9 October 2014, under a small log in the mud of the stream bed. When uncovered, a female was standing over the majority of her larvae, facing a *Eurycea bislineata* (Northern Two-lined Salamander) at the back of the nest (Fig. 1). Thirteen larvae were counted after both adult salamanders fled. By 10 October 2014 the female had returned, and 13 larvae were again observed. On the morning of 11 October 2014, both females from the above observations were absent from their nests. No larvae remained in the first nest; 13 were seen in the second, about half of which had begun to burrow into the mud. Female plethodontids may coil around eggs laid terrestrially, to help prevent desiccation (Wells 2007, *op. cit.*). The preceding observations are consistent with the possibility that female*s* may also use physical contact to help prevent the desiccation of aquatic larvae hatched in terrestrial nests, when water is not available.

FIG. 1. *Desmognathus fuscus* with developing larvae.

Larval attendance may also be exhibited by *D. fuscus* nesting in aquatic sites. On 29 October 2014, in the headwaters of an unnamed hillside spring 2.4 km from Bower's Spring (42.4645°N, 71.5759°W; WGS84), a female was found under a rock in a few cm of water with an aquatic larva (total length = 2.4 cm) adhered dorsolaterally above her rear leg. Another adult *D. fuscus* was present in the water at the edge of the cover rock. This observation, in addition to adult *E. bislineata* frequently seen approaching *D. fuscus* larvae at Bower's Spring, are consistent with the possible anti-predatory function of larval attendance. The observations in this note extend the period of aquatic larval parental care observed in *D. fuscus* from a few days to over one week, in the absence of water. The scope of larval attendance is also expanded to potentially include aquatic nest sites (Wells 2007. *op. cit*). Repeated observations of the brooding of aquatic larvae are useful to inform and motivate future studies.

JENNIE WILLIAMS (e-mail: jenniejwilliams@gmail.com), 21 Aldersey St. #4, Somerville, Massachusetts 02143, US

***DESMOGNATHUS QUADRAMACULATUS* (Black-bellied Salamander). PREDATION.** Trout are known predators on the various life stages of salamanders (Petranka 1998. Salamanders of the United States and Canada. Smithsonian Inst. Press, Washington DC. 587 pp.) and, in some cases, there are strong interactions between trout species and salamanders that can influence co-occurrence within streams (Resetarits 1997. Ecology 72:1782–1793). Most literature reporting these interactions focus on *Oncorhynchus mykiss* (Rainbow Trout) and two salamander species (e.g., *Ambystoma macrodactylum* and *A. gracile*, reviewed by Dunham et al. 2004. Fisheries 29:18–26) from the Western United States.

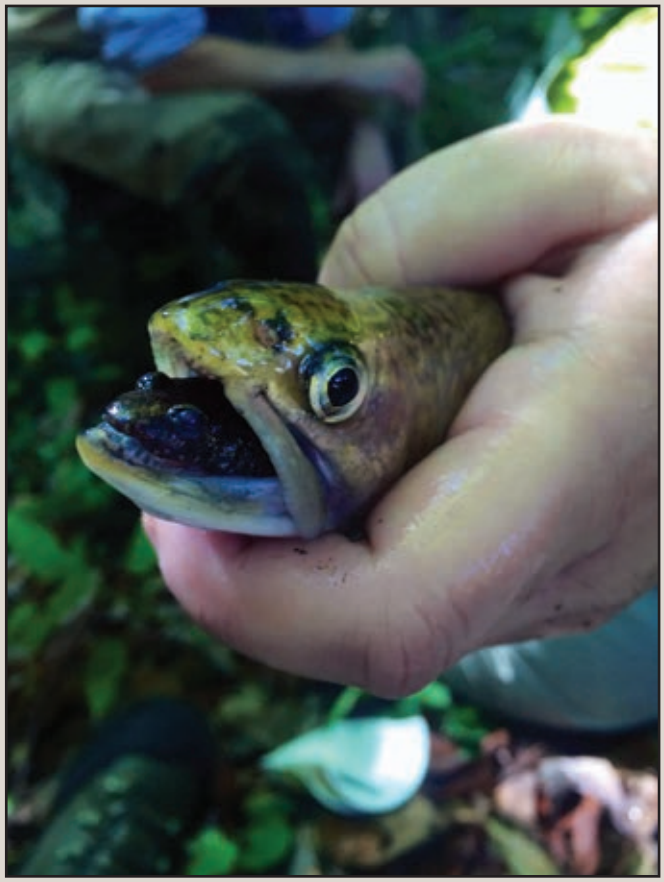

FIG. 1. Predation of an adult salamander *Desmognathus quadramaculatus* by an adult *Salvelinus fontinalis*.

On the afternoon of 08 October 2014, an adult *Salvelinus fontinalis* (Brook Trout; total length = 19.69 cm) was captured via electrofishing in Left Prong Hampton Creek in Carter Co., Tennessee, USA (36.1467°N, 82.0491°W, WGS84; 983 m elev.) with an adult *Desmognathus quadramaculatus* (total length = 10.80 cm) protruding from its mouth (Fig. 1). The salamander was desceased (photo voucher APSU 19530) and its tail was partially digested; therefore, the predation event preceeded our disturbance of the aquatic habitat and this event should be considered natural. This report is the first confirmed predation on *D. quadramaculatus* by *S. fontinalis* (Petranka 1998, *op. cit.*). However, because the elevational distribution of *D. quadramaculatus* (341–1829 m elev.; Dodd 2004. The Amphibians of Great Smoky Mountains National Park. University of Tennessee Press, Knoxville, Tennessee. 283 pp.) overlaps with both *S. fontinalis* and the introduced *O. mykiss* in the southern Appalachian Mountains, our finding is probably more common than reported in the literature.

JOSHUA R. ENNEN (e-mail: jre@tnaqua.org), **BERNIE R. KUHAJDA**, **KATHLINA F. ALFORD**, and **SARAH C. HAZZARD**, 201 Chestnut Street, Tennessee Aquarium Conservation Institute, Chattanooga, Tennessee 37402, USA.

***HEMIDACTYLIUM SCUTATUM* (Four-toed Salamander). POLYEMBRYONY.** Polyembryony in amphibians has been examined in vitro, but rarely observed in situ, especially in caudates. Natural observations of twinning in *Ambystoma tigrinum*, as three polyembryonic eggs, each containing two embryos, were observed from 1987–1988 (Lindberg 1995. Herpetol. Rev. 26:142). However, polyembryony has not been documented in Plethodontid salamanders. We report the first known observation of polyembryony in Plethodontid salamanders and specifically from *Hemidactylium scutatum*.

FIG. 1. Polyembryonic egg of *Hemidactylium scutatum*.

From 2007–2012 we located 369 nests of *H. scutatum* and examined 14,379 eggs from a site in Sullivan Co., Tennessee (36.52266°N, 82.11073°W; WGS84). On 09 April 2011 we found a joint nest with a single female (SVL = 38.7 mm; total length = 88.6 mm) guarding eggs in which one egg had two embryos (Fig. 1) while the remaining 64 eggs in the nest, and all other eggs located at the study site, contained a single embryo. At the time of discovery both embryos appeared to be at Harrison stage 36 (Harrison 1969. Organization and Development of the Embryo. Yale University Press, New Haven, Connecticut. 290 pp.).

The polyembryonic embryos differed in size during development and immediately after hatching (on 10 May 2011), when one embryo was 12.7 mm total length and the other was 13.8 mm. Mean total length from a sample of 12 *H. scutatum* larvae, randomly selected from ~600 larvae collected from 56 nests in 2011, was 13.3 mm (range: 12.1–16.0 mm). All eggs within the nest containing the *H. scutatum* polyembryonic egg hatched within one hour of a rain event. Our observations of *H. scutatum* hatching during this project indicated that most (> 90%) eggs from the same nest hatched within one hour of the first egg hatching. Both larvae from the polyembryonic egg were placed in mesocosm pools after hatching and no additional observations were made.

M. KEVIN HAMED, Virginia Highlands Community College, P.O. Box 828, Abingdon, Virginia 24212, USA (e-mail: khamed@vhcc.edu); **MATTHEW J. GRAY**, Department of Forestry, Wildlife and Fisheries, Institute of Agriculture, University of Tennessee, 274 Ellington Plant Sciences Building, Knoxville, Tennessee 37996, USA; **THOMAS F. LAUGLIN**, Department of Biological Sciences, East Tennessee State University, Box 70703, Johnson City, Tennessee 37614, USA.

***SIREN INTERMEDIA* (Lesser Siren). MASS AESTIVATION AND ARTIFICIAL HIBERNACULA.** *Siren intermedia* is a large (max. recorded length 686 mm) eel-like aquatic salamander distributed across the southeastern United States westward to eastern Texas and the lower Rio Grande Valley and northward through the Mississippi Valley to Illinois and Indiana (Martof 1973. Cat. Amer. Amphib. Rept. 127:1–3; Conant and Collins 1998. A Field Guide to Reptiles and Amphibians: Eastern and Central North America. 3rd ed. Houghton Mifflin Co., Boston, Massachusetts. 616 pp.). *Siren*

intermedia exhibits burrowing behavior during winter periods when temperatures become too low for ectothermic activity and also in response to drought conditions (Cagle and Smith 1939. Copeia 1939:232–233; Gehlbach et al. 1973. Am. Midl. Nat. 89:455–463). Large winter aggregations in northern parts of the species' range have been previously reported (Cagle and Smith 1939. Copeia 1939:232–233; Cockrum 1941. Copeia 1941:265).

Herein we report on a large aggregation of aestivating *Siren intermedia* discovered during an excavation on 18 November 2011 in Kleberg Co., Kingsville, Texas, USA (27.5417°N, 97.8803°W, WGS84). The excavated area was ~ 5 x 6 m and 0.25 m deep (Fig. 1) and had been dry for several months. A total of 73 individuals of varying size and sex were recovered from the site (Table 1). Unfortunately, many of the specimens were dead or had received serious injuries meriting euthanasia. For these specimens, primary sex organs were removed and processed for further study. Sex was not determined for the uninjured individuals that were released ~330 m SSW of the original capture site, in a small pond which during periods of higher rainfall is part of the same wetland area.

TABLE 1. Morphometric data of aestivating *Siren intermedia* from Kleberg County, Texas.
A. Mass data collected from specimens without injuries precluding accurate measurements.

Sex	Body mass (g)				Gonad mass (g)			
	N	Mean	s	Range	N	Mean	s	Range
Male	12	267.56	89.8	290.9	16	0.75	0.4	1.3
Female	6	219.05	33.9	94.2	9	5.13	4.4	14.5
Undetermined	34	186.87	79.8	343.3	–	–	–	–

B. Length data collected from specimens without injuries precluding accurate measurements.

Sex	Snout–vent length (cm)				Total length (cm)			
	N	Mean	s	Range	N	Mean	s	Range
Male	14	33.6	4.6	17.0	12	47.6	5.4	19.0
Female	7	33.0	1.6	5.0	7	44.3	2.7	7.5
Undetermined	34	31.1	4.2	18.8	34	44.2	5.9	23.2

FIG. 1. Excavation site of large aggregation of aestivating *Siren intermedia*. The area was ~ 5 x 6 m and 0.25 m deep.

FIG. 2. Concrete block with aestivating *Siren intermedia*.

The excavated area had several shallow cavities or fissures in which sirens had burrowed. In addition, there were numerous concrete blocks distributed throughout the area that contained sirens. The sirens were utilizing the hollow spaces in the blocks as artificial hibernacula (Fig. 2). We hypothesize that the blocks retained moisture and provided refuge from desiccation as well as predation. This is the first report of a large aggregation of sirens in the southern range of the species and the first report from Texas. In addition, this is the first report of artificial refugia utilized by this species.

RANDY L. POWELL (e-mail: randy.powell@tamuk.edu), **ASHTON V. CROCKER**, **SHAWNDA L. KUMRO**, **ROBERT W. RABE**, **ERIC O. MONTALVO**, Department of Biological and Health Sciences, Texas A&M University-Kingsville, 700 University Ave., MSC 158, Kingsville, Texas 78363, USA.

***SIREN INTERMEDIA NETTINGI* (Western Lesser Siren). DIET.** A summary of the natural history and ecology of *Siren intermedia* was provided in a species account (Martof 1973. Cat. Amer. Amphib. Rept. 127.1–127.3); information on its food habits were reported by Davis and Knapp (1953. Copeia 1953:119–121), Scroggin and Davis (1956. Herpetologica 12:231–237), and Altig (1967. Amer. Midl. Nat. 77:239–241). Concerning fish prey, lesser sirens have been reported to feed on minnows (Hurter 1911. Trans. St. Louis Acad. Sci. 20:59–274), been caught on hook and line by anglers using minnows as bait (Goin 1957. Herpetologica 13:37–42; Scroggin and Davis 1953, *op. cit.*), and fish scales have been found in their stomach (Altig 1967, *op. cit.*). Herein we document a noteworthy report of a threatened fish species in the diet of *S. i. nettingi*.

Nineteen juvenile and adult *S. i. nettingi* (mean ± SE SVL = 176.4 ± 59; range = 61–264 mm) were collected between June 1990 and April 1994 with minnow traps, dip nets, or by hand from a small tributary of the Caddo River, located 3.2 km W Caddo Gap off St. Hwy 8, at Caddo Hills High School, Montgomery Co., Arkansas, USA (34.4057°N, 93.6248°W, WGS84). Sirens were euthanized with a dilute chloretone solution and dissected for

analysis of stomach contents. Siren voucher specimens were deposited in the Arkansas State University Museum Herpetological Collection, State University, Arkansas (ASUMZ 16448–49, 16769, 17001, 17300–03, 17489–94, 19573–74). Specimens of darters are deposited in the Southern Arkansas University Fish Collection (SAU), Magnolia, Arkansas.

Six of 19 *S. i. nettingi* contained 18 individual vertebrate prey items in various stages of digestion in their stomachs. All items were subsequently identified as adult *Etheostoma pallididorsum* (Paleback Darter). Larger sirens consumed most of the darters; all (N = 6) sirens containing darters in their stomachs were ≥185 mm SVL whereas no sirens ≤173 mm SVL contained darters. Predator SVL (mm) and respective prey numbers are as follows: 185: 4, 190: 1, 232: 1, 235: 1, 250: 6, and 252: 5. Four female darters in the stomach contents of sirens collected in February 1991 were gravid, containing numerous ripe ova, coinciding with reports of spawning in the species in February and March (Robison and Buchanan 1988. The Fishes of Arkansas. The University of Arkansas Press, Fayetteville, Arkansas. 536 pp.). Of the darters eaten by sirens, 100% were consumed in February and March. The Paleback Darter is a threatened species in the state (listed S2) and is globally listed G2 (http://www.natureserve.com; 28 Jan 2015) due to its limited distribution (four counties) and small population size. Predation by sirens at sites known to support spawning of *E. pallididorsum* should now be considered as a possible negative impact on the species. Recent surveys (B. Crump, pers. comm.) have shown that *E. pallididorsum* still persists at the site herein.

We thank the Arkansas Game & Fish Commission for a Scientific Collecting Permit issued to SET, Jacob Sawyer (ASUMZ) for assistance in necropsies, and Betty Crump (Ouachita National Forest) for information on Paleback Darters.

ANURA — FROGS

***AGALYCHNIS CALLIDRYAS* (Red-eyed Tree Frog) and *CRUZIOHYLA CALCARIFER* (Splendid Leaf-frog). REPRODUCTIVE BEHAVIOR.** *Cruziohyla calcarifer* is a nocturnal canopy tree frog that can be found in primary lowland forests from Honduras to Ecuador. It is a medium-sized frog (males to 81 mm SVL, females to 87 mm) that reproduces in puddles among large fallen trees (Caldwell 1994. Herpetol. Nat. Hist. 2:57–66). It is an under-studied species because it is nocturnal and favors the canopies, however, habitat destruction, pet trade collecting, and crop spraying are believed to be steadily reducing these primary forest obligates (Coloma et al. 2008. www.iucnredlist.org; 6 Apr 2015). *Agalychnis callidryas* is also a nocturnal tree frog that can be found in lowland and premontane slopes from Mexico to Panama. Males can reach up to 59 mm SVL and females 77 mm (Savage 2002. The Amphibians and Reptiles of Costa Rica. University of Chicago Press, Chicago, Illinois. 934 pp.). It deposits eggs on vegetation overhanging puddles and pools of water (Savage 2002, *op. cit.*). Although it is commonly found in the pet trade, it is known to thrive in secondary forests and areas with some human alteration.

FIG. 1. A male *Agalychnis callidryas* in amplexus with a male *Cruziohyla calcarifer* in Sarapiqui, Costa Rica.

Atypical amplexus has been found repeatedly in anurans, ranging from male-male amplexus (Mollov et al. 2010. Biharean Biologist 4:121–125), interspecific amplexus (Lamb et al. 1990. J. Evol. Biol. 3:295–309), necrogamy (Gomez-Hoyos et al. 2012. Herpetol. Notes 5:497–498), and amplexus with inanimate objects (Streicher 2008. Herpetol. Rev. 39:75). While less common than interspecific amplexus, intergeneric amplexus has been reported in both tropical and temperate species (e.g., Grogan and Grogan 2011. Herpetol. Rev. 42:89–90; Manzano and Corzas 2011. Herpetol. Rev. 42:84; Stynoski et al. 2013. Herpetol. Rev. 44:129–130). As a means of reproductive interference, intergeneric amplexus has been found to have adverse fitness and evolutionary effects for at least one of the species and can lead to sexual exclusion, spatial, temporal, or habitat segregation, changes in life history parameters, and reproductive character displacement (Gröning and Hochkirch 2008. Q. Rev. Biol. 83:257–282). Here, we report amplexus between two male individuals from unrelated taxa.

At ca. 1900 h on 21 April 2013 a male *A. callidryas* was observed in amplexus with a male *C. calcarifer* (Fig. 1) in a private forest in Sarapiqui, Costa Rica (10.4358°N, 84.0445°W, WGS84; 35 m elev.). The frogs were found at the edge of a clearing adjacent to a primary forest that has experienced selective logging within the last 20 years. They were sighted about 2.5 m high on a branch.

D. BLAINE MARCHANT (e-mail: dbmarchant@ufl.edu), Biology Department, University of Florida, Gainesville, Florida 32611, USA; **TESS HERMAN** and **ADAM C. STEIN**, Council for International Educational Exchange, Monteverde, Costa Rica.

***ANAXYRUS AMERICANUS* (American Toad). ARBOREAL BEHAVIOR.** *Anaxyrus americanus*, a species native to the eastern United States and Canada, is highly terrestrial (Dodd 2013. Frogs of the United States and Canada. Johns Hopkins University Press, Baltimore, Maryland. 962 pp.). Few accounts of arboreal behavior or habitat use have been reported for North American bufonids (but see Kornilev 2007. Herpetol. Rev. 38:319). We made the following observation of arboreal behavior by a juvenile (estimated SVL = 2.5–3.0 cm) *A. americanus* the day after a rain event in a mixed deciduous forest near a stream in central Columbia Co., Pennsylvania, USA (41.0710°N, 76.4080°W; WGS84). At 1400 h on 10 September 2014, a juvenile *A. americanus* retreated from the forest floor to a longitudinal

PHOTO BY MARISA M. BUCKLE.

FIG. 1. American Toad (*Anaxyrus americanus*) suspended within a longitudinal crevice in a White Oak (*Quercus alba*) tree.

crevice approximately 50 cm off of the ground on the external surface of the trunk of a mature White Oak tree (*Quercus alba*). The toad braced itself by pushing its feet against opposing walls of the crevice (Fig. 1). The walls of the crevice were textured due to the tree's bark. The toad had been active on the forest floor and was disturbed by our walking near where it had been originally located. Several other juvenile toads were also observed within the same general area (< 2 m from the tree). Even though we did not approach the tree for at least 30 min. following the initial observation and no attempts were made to capture the toad, the toad remained suspended in the crevice until after we left the area. *Anaxyrus americanus* are known to rely on camouflage and immobility as means of predator avoidance (Dodd 2013, *op. cit.*). The observed toad remained immobile and was well camouflaged in the bark-lined crevice. Additionally, by retreating to a location approximately 50 cm above the forest floor, the toad may avoid common terrestrial predators, such as *Heterodon platirhinos* (Eastern Hog-nose Snakes).

AMBER L. PITT (e-mail: apitt@bloomu.edu), **MARISA M. BUCKLE**, **ERICK N. WAHLMAN**, **VICTORIA E. DITOMO**, Department of Biological and Allied Health Sciences, Bloomsburg University, Bloomsburg, Pennsylvania 17815, USA.

***ECNOMIOHYLA MIOTYMPANUM* (Small-eared Treefrog) and *INCILIUS CRISTATUS* (Large-crested Toad). HETEROSPECIFIC AMPLEXUS.** Overlap in breeding microhabitat and phenology in anurans can lead to male amplexus of heterospecifics (e.g., Yadav and Yankanchi 2014. Herpetol. Rev. 45:683). This behavior appears to be driven, at least in part, by lack of selectivity in male anurans—even to the point of males amplexing dead conspecifics (e.g., Ayers 2010. Herpetol. Rev. 41:192–193) or inanimate objects (Streicher 2008. Herpetol. Rev. 39:75). Heterospecific amplexus by a male *Ecnomiohyla miotympanum* on a female *Charadrahyla taeniopus* has been previously reported (Luría Manzano and Vázquez Corzas 2011. Herpetol. Rev. 42:84). Here, we report the second known case of heterospecific amplexus by *E. miotympanum*, this time on the rare bufonid *Incilius cristatus*.

On 25 November 2013 at 2150 h, we observed a male *E. miotympanum* engaging in axillary amplexus with a male *I. cristatus* (Fig. 1) at Rancho el Jacal, a private reserve 6.2 km NNE of

PHOTOGRAPH BY ADAM G. CLAUSE

FIG. 1. Heterospecific amplexus between male *Ecnomiohyla miotympanum* and male *Incilius cristatus*.

Atzalán, Municipality of Atzalán, Veracruz, México (19.8437°N, 97.2250°W, WGS84; 1170 m elev.). The frogs were occupying the fringes of a ca. 10-m-diameter side pool of the Río Alceseca, on a sandy/silty substrate in water less than 5 cm deep. The *I. cristatus* male did not appear to be disturbed by the *E. miotympanum*; neither frog moved during the 15 min we observed them. Dozens of *E. miotympanum* were chorusing nearby, and seven adult *I. cristatus* also occupied the pool. Multiple conspecific amplexing pairs of both species were present, and we also noted eggs and/or tadpoles of the two species in the pool.

A photographic voucher was deposited in the Natural History Museum of Los Angeles County (LACM PC 1830) and was verified by Joseph R. Mendelson. We thank Sr. Jacobo Alvarez for land access. Financial support provided by a University of Georgia Presidential Fellowship.

***ENGYSTOMOPS PETERSI* (Peter's Dwarf Frog). PREDATION.** Spiders and other invertebrates are known predators of anurans. Numerous records of *Ancylometes* sp. (fishing spiders) predating neo-tropical anurans exist (e.g., *Dendrophsophis elegans, D. minutus, D. sarayacuensis, Scinax alter, Smilisca sordida*; Prado and Borgo 2003. Herpetol. Rev. 34:238–239; Menin et al. 2005. Phylomedusa 4:39–47; Toledo 2005. Herpetol. Rev. 36:395–400; Rodrigues and Arruda 2007. Herpetol. Rev. 38:437; Serafim et al. 2007. Herpetol. Rev. 38:437; Dehling 2007. Herpetol. Rev. 38:444). Predation events on members of the genus *Engystomops* by invertebrates and vertebrate species such as bats have been recorded (Gray et al. 1999. Herpetol. Rev. 30:93; Toledo 2005, *op. cit.*; Trillo et al. 2013. J. Evol. Biol. 26:216–222). However, records of predation events on *E. petersi* are lacking. We report here an observation of an *Ancylometes* sp. predating a *E. petersi*.

At 2140 h on 12 June 2012 we observed a spider feeding on an adult *E. petersi* (Fig. 1) near a small, closed canopy stream near the San Antonio Guard Station, Heath River, Madre de

FIG. 1. A Fishing Spider, *Ancylometes* sp., preying on a Peter's Dwarf Frog, *Engystomops petersi*, in Peru.

Dios, Peru (12.66008°S, 68.74042°W, WGS84; 181 m elev.). The individuals were approximately 3 m from the stream on a steep muddy bank. When first observed the frog appeared to be dead and bloated with the spider's fangs piercing its lower abdomen. When approached, the spider behaved defensively by rearing back its front legs and spreading its pedipalps. It then attempted to retreat under a cavity of the bank while carrying the frog. The duration of the observation was approximately 7 min.; the frog was collected before the spider could escape and deposited at the herpetology collection of the Centro de Ornitologia y Biodiversidad in Lima, Peru (FF3306).

We thank Asociacion Fauna Forever for field support, volunteer Daniel Prado, intern Rueben Culqui, and Idelfonso Vargas of SERNANP.

***HYLARANA NIGROVITTATA* (Black-striped Frog). DEATH FEIGNING BEHAVIOR.** A wide range of predators, especially snakes, consume frogs. To avoid predation, amphibians have developed various types of defensive strategies such as thanatosis, stiff-leggedness, lung inflation, toxic secretions, contraction and body raising (Duellman and Trueb 1986. Biology of Amphibians. New York, McGraw-Hill. 670 pp.; Toledo et al. 2011. Behavioural Defences of Anuran: An Overview. Ethol. Ecol. Evol. 23:1–25). *Hylarana nigrovittata* is a medium-sized ranid that occurs in Cambodia, China, India, Indonesia, Laos, Malaysia, Myanmar, Thailand and Vietnam (www.iucnredlist.org; 15 Dec 2014). Defensive behaviors have not yet been reported in *H. nigrovittata*. Herein I document for the first time, death feigning behavior exhibited by *H. nigrovittata* from Kedah, Malaysia.

FIG. 1. Death feigning behavior displayed by *Hylarana nigrovittata*.

Between 2100 and 2200 h on 17 May 2014, five adult *H. nigrovittata* were collected near the rockpools at the edge of Sungai Sedim, Kedah (5.2506°N, 100.4651°E, WGS84; <200 m elev.). All specimens were brought back to the laboratory and measured. When handled and approached during photography, two frogs exhibited defensive postures, while the other specimens did not show any. The first frog (SVL = 41.2 mm; 7 g) exhibited death feigning behavior (thanatosis). The specimen leapt away when placed on the ground; after several leaps, the frog suddenly flattened its body, laid down on its back on the dead leaves and stretched out its legs (Fig. 1). The individual remained in this motionless posture with both eyes open for about 90 s before assuming its normal posture and leaping away. The second frog (SVL = 43.4 mm; 8 g) also displayed death feigning behavior. When approached, the frog suddenly turned on its back and inflated its body. It stayed in this motionless position with both eyes open for about 120 s, then assumed normal posture and leapt away. Later the two specimens were euthanized, tagged, fixed with 10% formalin, stored in 70% ethanol and deposited at School of Pharmacy, Universiti Sains Malaysia (14USM-SS-HN01, 02).

I wish to express our heartfelt gratitude to Universiti Sains Malaysia, Penang for all the facilities and amenities provided. This project was funded by Universiti Sains Malaysia, Short Term Grant (304/PFARMASI/6312127).

SHAHRIZA SHAHRUDIN (e-mail: shahriza20@yahoo.com), School of Pharmaceutical Sciences, Universiti Sains Malaysia, 11800 Penang, Malaysia.

***HYPSIBOAS FABER* (Blacksmith Treefrog). PREDATION.** *Hypsiboas faber* is a medium sized Neotropical hylid that occurs widely in the Atlantic Forest of Brazil, Argentina and Paraguay. Although its natural history is well known, there are few predation events reported (Martins et al. 1993. Amphibia-Reptilia 14:307–309). Antbirds are exclusively Neotropical passerines widely distributed in forested environments and woodlands. They feed predominantly on arthropods, however, larger genera (e.g., *Mackenziaena*, *Taraba*, *Frederickena*, and *Batara*) are known to prey on vertebrates such as small snakes, lizards, frogs, rats, and nestlings (Sick 1997. Ornitologia Brasileira. Editora Nova Fronteira. Rio de Janeiro, Brazil. 912 pp.).

On 18 August 2013, in an Atlantic Forest area at Serra dos Tucanos lodge, Cachoeiras de Macacu municipality, Rio de Janeiro state, southeastern Brazil (22.3143°S, 42.3733°W; WGS84), an adult male *Batara cinerea* (Giant Antshrike) was seen at the forest edge foraging within the leaf litter. Suddenly we heard a continuous and squeaky vocalization. We approached and noticed that the bird was trying to catch an adult *H. faber* that was on a branch about 3 m above the ground. The frog managed to jump to the ground in an attempt to escape from the predator, which then rapidly pursued the prey and approached within about 50 cm of the observers. The frog continued to emit the distress call before being captured by the *B. cinerea*, which began pounding the prey against the leaf litter and a near branch (Fig. 1). After subjugating

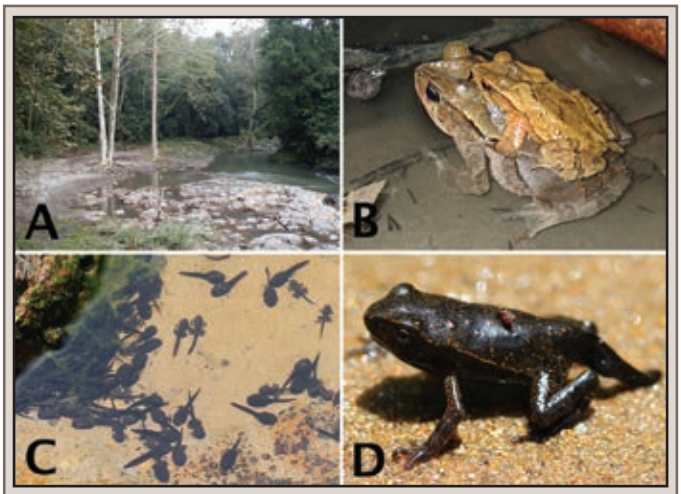

FIG. 1. *Hypsiboas faber* being preyed upon by a Giant Antshrike (*Batara cinerea*)

and killing the frog, the antbird disappeared among the bushes and the subsequent scenes could not be monitored.

This note is only the third documented predation event of *H. faber* by an avian species. The other two records—both unsuccessful—also occurred in Atlantic Forest of southeastern Brazil: a *Tyto furcata* (Barn Owl) was observed attempting to prey upon an adult male (Martins et al. 1993. Amphibia-Reptilia 14:307–309), and the other reported *Micrastur ruficollis* (Barred Forest Falcon) holding an adult of *H. faber*, but it released the prey due to the presence of the researchers (Santos et al. 2013. Herpetol. Not. 6:313–315).

***INCILIUS CRISTATUS* (Large-crested Toad). REPRODUCTIVE BEHAVIOR.** *Incilius cristatus* is an enigmatic species known only from the cloud forests of central Puebla and Veracruz, México (Mendelson 1998. Cat. Amer. Amphib. Rept. 646:1–2). This species breeds in streams (Mendelson 2011. Zootaxa 3138:1–34), but its reproductive biology and early life stages remain otherwise poorly known (Mendelson 1997. Herpetologica 53:268–286). Altig (pers. comm., cited in Mendelson 1997, *op. cit.*) collected tadpoles of *I. cristatus* from boulders of fast moving streams in late December. Recently, a captive breeding project at Africam Safari in Puebla reported successful laboratory reproduction of *I. cristatus* (Hernández Díaz 2013. Amphib. Ark Newsl. 2013:17). The authors also noted wild breeding at the source population in Barranca de Xocoyolo, Puebla—but provided no specifics (Hernández Díaz 2013, *op. cit.)*. Importantly, only seven extant populations of *I. cristatus* are formally documented: Barranca de Xocoyolo; Cascada de La Gloria, Puebla (Mendelson and Canseco Márquez 1998. Herpetol. Rev. 29:106); 6 km S of Huatusco and 3 km NE of Coscomatepec, Veracruz (Meza Parral 2013. Master's Thesis, Instituto de Ecología, A.C. México); and three populations near Xalapa, Veracruz (Pineda and Halffter 2004. Biol. Conserv. 17:499–507). Here, we provide reproductive data for *I. cristatus* from a newly re-discovered population in east-central Veracruz.

PHOTOS BY ADAM G. CLAUSE

FIG. 1. A) Breeding habitat for *Incilius cristatus*; B) Amplexing *I. cristatus*; C) *I. cristatus* tadpoles; D) *I. cristatus* metamorph.

On 25 November 2013 from ca. 2130–2210 h, we observed breeding by *I. cristatus* at Rancho el Jacal, a private reserve ca. 6.2 km NNE of Atzalán, Municipality of Atzalán, Veracruz, México (19.8437°N, 97.2250°W, WGS84; 1170 m elev.). Occupied microhabitat was a ca. 10-m-diameter side pool of the Rio Alceseca, a tributary to the Rio Filobobos, in old-growth cloud forest (Fig. 1A). In this pool, we counted four lone males, two amplexing pairs, and an estimated 10,000 young tadpoles congregating around spent egg-string jelly. The lone males occupied the fringes of the pool in water less than 5 cm deep. The amplexing pairs were resting on the bottom of the pool in water at least 20 cm deep. We gently moved one pair to shallower water for photographic documentation (Fig. 1B). The spent egg strings were attached to fallen dead branches and leaf litter of Mexican plane trees, *Platanus mexicana*. All eggs were hatched. All tadpoles appeared to be the same age (Gosner Stage 25 or lower), and were resting motionless on the pool's sandy/silty substrate. We conservatively estimate these eggs were laid by a dozen female *Incilius cristatus*, based on a maximum captive output per female of 856 eggs (Hernández Díaz 2013, *op. cit.*). Dozens of *Ecnomiohyla miotympanum* (Small-eared Treefrogs) were also breeding in the vicinity. Although the *E. miotympanum* were actively chorusing, we never heard calls from other anuran species. This supports the prediction by Mendelson (1997, *op. cit.*) that *I. cristatus* may lack an advertisement call. A fine drizzle was falling the night of our observations. Two days prior, a moderate to heavy rain had fallen at the site for ca. 12 hours.

We returned to Rancho el Jacal on 5–10 April 2014 and observed *I. cristatus* tadpoles (Fig. 1C) and metamorphs (Fig. 1D) at the original breeding site and at an eddy 100 m downstream that we had not visited in November. The tadpoles were gregarious, congregating alongside *E. miotympanum* tadpoles on rocks or silty substrate in areas of low-velocity flow, less than 0.5 m deep. We noted two distinct age classes at each site: Gosner Stage 42–45 and 36–39. This evidence suggests that populations of *I. cristatus* may deposit eggs several times per year rather than in a single, explosive event.

We also report *I. cristatus* elsewhere in the vicinity: an adult in Atzaán near the Church of Fatima 6.6 km SSW of Rancho el Jacal in February 2012 (19.78783°N, 97.24508°W, WGS84; 1700 m elev.); two juveniles in a side-pool of the Rio Alceseca 1.3 km SSE of Rancho el Jacal in April 2012 (19.83403°N, 97.22085°W, WGS84; 1220 m elev.); and over two dozen other adults, juveniles, and

metamorphs at Rancho el Jacal from 13 June 2012 to 18 July 2014, all within 0.5 km of the observed breeding sites. These records are the first confirmation of *I. cristatus* from this region since Ronald Altig collected tadpoles of *I. cristatus* near Atzalán in 1969 (UMMZ 151887) and 1970 (UMMZ 151571). Our observations indicate that the Río Alceseca near Atzalán supports a robust *I. cristatus* population, and is of significant conservation importance for this IUCN Critically Endangered species (IUCN Red List 2013, www.iucnredlist.org, accessed 30 January 2014).

Photographic vouchers (LACM PC 1828–1833) were deposited in the Natural History Museum of Los Angeles County and were verified by Joseph R. Mendelson. We thank Sr. Jacobo Alvarez for land access, and Joseph R. Mendelson for his initial review of this note. Financial support was provided by a University of Georgia Presidential Fellowship.

CLAUSE, Warnell School of Forestry and Natural Resources, University of Georgia, 180 East Green Street, Athens, Georgia 30602, USA (e-mail: adamclause@gmail.com); **KARLO ANTONIO SOTO HUERTA**, Rescatando Pancho Poza y su Biodiversidad A. C., Dr. Marin N° 2, Colonia Centro, Apartado Postal 93700, Altotonga, Veracruz, México; **MALCOLM A. GREELEY**, 15282 Campus Park Drive, Unit D, Moorpark, California 93021, USA.

***LEPTODACTYLUS LABYRINTHICUS* (Pepper Frog). DIET.** We observed a predation attempt on *Erythrolamprus reginae* (Royal Ground Snake) by a *Leptodactylus labyrinthicus* on 15 December 2012 in the Environmental Protection Area in the Serra do Lajeado, Palmas, Tocantins, Brazil (10.1221°S, 48.1911°W, SAD69; 655 m elev.). The predation event was observed at an artificial pond associated with a stream at a forest edge. The snake struggled to escape while the anuran held the prey with its mouth and handled it with its right hand (Fig. 1). We observed the event for ca. 2 min. The snake escaped from the frog and entered the water immediately after the photograph was taken. We presume that the frog released the snake due to the large size of the prey, but it is possible that our presence caused the snake's release. We collected and measured the frog (SVL = 138.2 mm) and deposited it in the Herpetological Collection of the Universidade Federal de Goiás (ZUFG 7454).

Predators can have foraging strategies that maximize energy acquisition, such as capture of large prey. However, bigger prey require longer handling times, larger energy expenditure, and longer exposure to other predators, thus, there are trade-offs associated with acquiring large prey (Sazima and Martins 1990. Mem. Inst. Butantan 52:73–79). Different groups of vertebrates have been recorded in the *L. labyrinthicus* diet, including snakes (Vaz-Silva et al. 2003. Herpetol. Rev. 34:359; Fonseca et al. 2012. Herpetol. Notes 5:167–168). Although we did not observe the consumption of the prey, we considered that *E. reginae* is a potential prey for *L. labyrinthicus*, making our record the first such observation involving these two species.

FIG. 1. Predation attempt on *Erythrolamprus reginae* by *Leptodactylus labyrinthicus* in the APA Serra do Lajeado, Tocantins, Brazil.

We are grateful to Girinos do Brasil (Edital SISBIOTA: grants CNPq 563075/2010-4 and FAPESP 2010/52321-7) for financial support in the field sampling, Naturatins for logistical support and Reuber A. Brandão for helping identify the snake.

***LEPTODACTYLUS SAVAGEI* (Savage's Thin-toed Frog). REPRODUCTIVE BEHAVIOR.** An explosive breeding event of *L. savagei* was observed on 25–27 August 2004 inside the mature forest of Peninsula Gigante, Barro Colorado Natural Monument, Panama (9.1228°N, 79.8580°W, WGS 84; ca. 35 m elev.). The event took place in a temporary pond (ca. 13 m long, ca. 5 m wide, ca. 0.3 m maximum depth) formed during unusually heavy and continuous rainfall on 25 August 2004. The first night of observation there were between 160–180 active individuals, mainly near the shore of the pond, and almost 75% were males. Other frog species such as *Agalychnis callidryas* (Red-eyed Treefrog), *Dendropsophus ebraccatus* (Hourglass Treefrog), *D. microcephalus* (Yellow Cricket Treefrog), *Trachycephalus venulosus* (Veined Treefrog), *Engystomops pustulosus* (Tungara Frog), and *Chiasmocleis panamensis* (Panama Humming Frog) were also present at high densities.

I saw six *L. savagei* couples in amplexus that were approached closely (0.1–0.15 m) by conspecific satellite males. The amplectant males reacted to the interference by directing toward the satellite males a soft call of lower volume and shorter duration than the usual "whuup" of the advertisement call (Ibáñez et al. 1999. Los Anfibios del Monumento Natural Barro Colorado, Parque Nacional Soberanía y Áreas Adyacentes. Editorial Mizrachy y Pujol, Panamá. 187 pp.). In each display the amplectant males repeated the soft call 5–10 times in a shorter temporal frequency than when they repeat advertisement calls. Satellite males responded immediately with similar soft calls but with fewer repetitions than the amplectant males and the amplectant males again emitted the soft calls. In three of these encounters the satellite males moved away from the couple after the second acoustic display from amplectant males; but in the other three, the satellite males persisted with their soft calls. In one of these observations an amplectant male, separated from the female, repeated again the soft calls and the satellite male retreated. In the other two, the amplectant males also got off the female and repeated the soft calls, but satellite males responded by also displaying the soft calls and then both males commenced physical

combat, standing on their hind legs grappling with each other, scratching one another with thumb and chest spines, and finally each amplectant male grabbed the opponent by its ventrolateral region and threw it back over its head. In both cases the amplectant male then returned to amplex the female. Bloody wounds were clearly visible in the chest and lateral regions of the males involved in the combats, reinforcing the role of these spines as secondary sexual characters for use in male-male combat (Heyer 2005. Arq. Zool. 37:269–348). The combat behaviors observed here are similar to those described previously for *L. pentadactylus* during a similar explosive breeding event (Rivero and Esteves 1969. Breviora 321:1–14). Other congeners display additional calls besides their advertisement call. For example, *L. labyrinthicus* emit encounter calls probably to avoid combat with approaching males (Silva et al. 2008. CH 2008:1–6).

Explosive breeding of *L. savagei* is rarely seen and the interactions described here suggest that during reproductive events males of this species can display additional calls (besides their advertisement calls) that may function as encounter or aggressive calls that drive male-male combat when competing for a female. Further research is required to define the function and acoustic characteristics of these calls.

LUIS ELIZONDO-LARA, Programa de Maestría en Ciencias Biológicas, Vicerectoría de Investigación y Postgrado, Universidad de Panamá, Avenida Simón Bolívar (Carretera Transistmica), Ciudad de Panamá, Panamá. Apartado 3366 Panamá 4, Panamá; e-mail: elizondolui@gmail.com.

***LITHOBATES SYLVATICUS* (Wood Frog). HABITAT USE.** *Lithobates sylvaticus* is the second most widely distributed anuran in North America (Martof and Humphries 1959. Am. Midl. Nat. 61:350–389), and its habitat use reflects the environmental variation that exists across its geographic range (Semlitsch et al. 2009. BioScience 59:853–862). Although *L. sylvaticus* post-breeding habitat selection has been described in Missouri (Rittenhouse and Semlitsch 2007. J. Herpetol. 41:645–653) and Maine (Baldwin et al. 2006. J. Herpetol. 40:442–453; Blomquist and Hunter 2010. Ecoscience 17:251–264), these studies did not report the species' use of glacial erratics, or boulders. We conducted our study in Maine's Nahmakanta Public Reserved Land (45.68210°N, 69.12940°W, WGS84; 407–530 m elev.), which is located in the Quebec/New England Boundary Mountains ecoregion.

We used radio telemetry to monitor 71 *L. sylvaticus* adults between 0635 and 1820 h during 12 May 2011–05 April 2013. Thirty-one frogs were monitored in 2011, 29 in 2012, 10 during 2011–2012, and one during 2011–2013. We observed seven (2011) and 12 (2012) frogs on boulders (maximum diameter > 2 m) during weekly relocations, and four (2012) frogs on large rocks (maximum diameter < 2 m). Most frogs were found on boulders only once or twice, however, one frog was found on multiple boulders during seven of 17 relocations during 13 July –15 October 2012. Boulders typically were covered with polypody ferns (*Polypodium* spp.), mosses, or lichen and leaf litter and downed woody debris. Boulders often had steeply-sloped sides (estimated > 70°) and ranged in height from 0.6 m to 2.1 m.

Boulders provide a unique microhabitat in the study landscape. Frogs on boulders were embedded in moist moss and lichen, which likely promoted thermoregulation and moisture retention via increased moisture availability and decreased solar radiation. We relocated one frog in small pools of water formed in the depressions at the base of boulders during three relocations and within 5 m of these pools during five other relocations. These depressions held water throughout much of the summer. Boulders may also provide refuge from predators. We commonly observed radio-tagged frogs bounding for rock and boulder crevices. Boulders are a microhabitat alternative to forest substrate litter for *L. sylvaticus* during the post-breeding period in Maine's montane landscapes. This unique landscape feature provides a moist refuge from predators not previously reported in habitat use and selection studies for this species.

***LITORIA CHLORIS* (Red-eyed Tree Frog). PREDATION.** Frogs are important prey items for many vertebrate and invertebrate species but predation by crustacea, such as freshwater crayfish, has rarely been reported in Australia (Pyke et al. 2013. Herpetol. Notes 6:195–199). In a review of the invertebrate predators of amphibians, crustacean predators included crabs and occasionally crayfish (Toledo 2005. Herpetol. Rev. 36:395–400; Wilson and Williams 2014. Toxicon 82:9–17). Here we note the predation of *Litoria chloris* (Red-eyed Tree Frog) by *Euastacus spinifer*, a freshwater spiny crayfish.

Litoria chloris is an arboreal hylid found across the subtropical to temperate forests of the east coast of Australia. Little is known of their ecology but it is suspected that they spend most of their lives foraging and living within the canopy of coastal rainforest and wet sclerophyll forests. As with many other arboreal hylid and rhacophorid anuran species, these frogs descend to the ground following heavy rain events to breed in ephemeral water bodies such as ponds, ditches, and pools (Anstis 2013. Tadpoles and Frogs of Australia. New Holland Publishers, Sydney. 829 pp.).

At 2230 h on 11 December 2014, following heavy rain (ca. 25 mm in less than 24 h), one such breeding event occurred in the Myall River State Forest near Bulahdelah, New South Wales, Australia. Along a 2-km stretch of unsealed road we

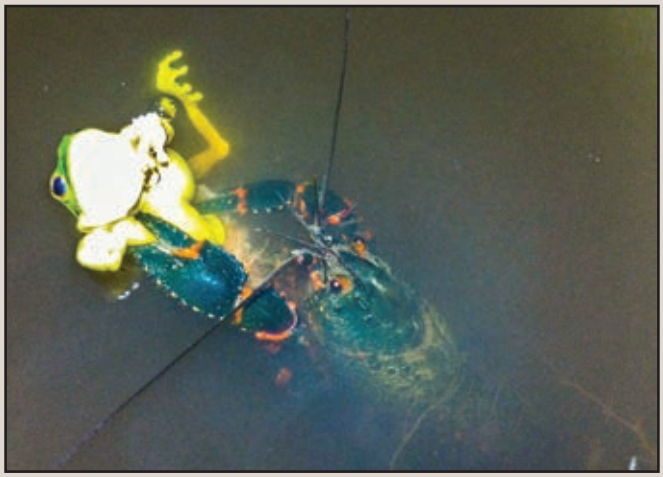

FIG. 1. *Euastacus spinifer* predating upon *Litoria chloris*.

observed several large congregations of breeding *L. chloris* in flooded roadside ditches and wheel ruts. At one site (32.3853°S, 152.1017°E; WGS84) at least 30 individuals were observed calling and amplecting. Amplectant pairs were observed on the ground with many chorusing males scattered around the water's edge and in low vegetation. The temperature was 18°C with 84% humidity. One frog was struggling in a water-filled wheel rut approximately 25 cm deep. On closer inspection we noticed that the frog (SVL = ca. 65 mm) had been seized by an adult freshwater crayfish (*E. spinifer*) approximately 16 cm in length (Fig. 1). The frog was severely wounded below the abdomen where it had been seized by the crayfish's claws. The struggle was observed for several minutes before the crayfish retreated to a deeper part of the pool with the frog and disappeared from sight. It is assumed that the frog was consumed as the next morning the same crayfish was sighted but not its prey.

Euastacus spinifer predominately occur in freshwater rivers and streams but may move away from larger water bodies during rain. They feed primarily on detritus, but are also known to feed on invertebrates and carrion (Turvey and Merrick 1997. Proc. Linn. Soc. NSW 118:175–185). They have also been reported feeding on tadpoles and small frogs (one unidentified species; Turvey and Merrick 1997, *op. cit.*). This instance clearly shows that they are also capable of taking larger vertebrate prey.

The aquatic breeding stage of a frog's life cycle is a significant period for predation by invertebrates (Toledo 2005, *op. cit.*). Given that *L. chloris* only descend from the canopy to breed, this may make them more vulnerable to a range of aquatic predators that do not normally pose a threat.

GEORGE MADANI, School of Biological Sciences, University of Sydney, New South Wales 2006, Australia (e-mail: chiro_ptera@hotmail.com); **TOM PARKIN**, Springwood, New South Wales 2777, Australia (e-mail: elapideco@gmail.com).

***LITORIA WILCOXII* (Stony Creek Frog). INTERSPECIFIC AMPLEXUS.** Interspecific amplexus is most commonly associated with explosive breeding species or those with a strongly male-biased operational sex ratio such as bufonids (Wells 2007. The Ecology and Behavior of Amphibians. University of Chicago Press, Chicago, Illinois. 1148 pp.). During the breeding season (spring to autumn), male *Litoria wilcoxii* gather along creek edges and call for prospective females (Donnellan and Mahony 2004. Aust. J. Zool. 52:1–28). There is a strong male-biased sex ratio within these aggregations (pers. obs.). This species undergoes rapid color change during amplexus, whereby males turn from brown to bright yellow within minutes after initiation of amplexus (Kindermann et al. 2014. PLoS ONE 9:e114120). Due to the strongly male biased sex ratio, access to females may be limited and intense male competition may occur. Here I document two cases of interspecific amplexus involving male *L. wilcoxii* and one native and one introduced anuran. The first observation (Fig. 1) occurred at 2056 h on 21 October 2013, where I observed a male *L. wilcoxii* amplecting a juvenile *Mixophyes iteratus* (Giant Barred Frog) along a rocky section of the Nerang River in Numinbah Valley, Queensland, Australia (28.1770°S, 153.2280°E, WGS84; 155 m elev.). The *M. iteratus* did not attempt to move away from or dislodge the male and the pair remained in this way for several hours. Air temperature was 20.5°C and water temperature was 24.2°C. The second case occurred in the same location at 2025 h on 4 November 2013, this time between a male *L. wilcoxii* and a *Rhinella marina* (Cane Toad). In this case a male *L. wilcoxii* was observed jumping towards the *R. marina*

FIG. 1. Amplexus between a male *Litoria wilcoxii* and juvenile *Mixophyes iteratus*.

FIG. 2. Amplexus between a male *Litoria wilcoxii* and *Rhinella marina*. A) Color at first sighting. B) Color 10 minutes later.

and immediately amplexing it; the *R. marina* made no attempt to dislodge the amplectant male. The pair remained in amplexus for several hours during which time the male *L. wilcoxii* underwent rapid color change from brown to yellow within 10 min. of amplexus initiation (Fig. 2). Air temperature was 19.6°C and water temperature 23.3°C. It is worth noting that several more observations of interspecific amplexus between male *L. wilcoxii* and *R. marina* were made during the breeding season, showing that this may be a common occurrence, despite not being documented in the literature. In all cases the amplected frog was a similar size and color to female *L. wilcoxii*, these observations indicate that males may be choosing females based on body size or color, the lack of females observed in the area might explain why males turn to other species.

CHRISTINA KINDERMANN, Environmental Futures Research Institute, School of Environment, Griffith University, Parklands Drive, Southport, QLD 4222, Australia; e-mail: christina.kindermann@griffithuni.edu.au.

***PELOPHRYNE ALBOTAENIATA* (Palawan Toadlet). MORTALITY.** *Pelophryne albotaeniata* is a small (SVL = 18–23 mm) endemic bufonid occurring in montane forest (1300–1600 m elev.) on Palawan Island, Philippines and is currently

listed as endangered in the IUCN Red List due to its limited distributional range (Diesmos et al. 2014. *In* Heatwole and Das [eds.], Conservation Biology of Amphibians in Asia, pp. 310–336. Natural History Publications [Borneo] Sdn. Bhd., Sabah, Malaysia). A few frog species including *Pelophryne misera* (Malkmus and Dehling 2008. Herpetozoa 20:165–172), *Kalophrynus pleurostigma* (Lim and Ng 1991. Raffles Bull. Zool. 39:209–214), *K. yongi* (Matsui 2009. Zoo. Sci. 26:579–585), *Microhyla borneensis* (Matsui 2011. Zootaxa 2814:33–49), and *M. nepenthicola* (Das and Haas 2010. Zootaxa 2571:37–52) have been documented utilizing carnivorous pitcher plants (*Nepenthes* spp.) as refugia and breeding sites. Herein we report on mortality of *P. albotaeniata* in a pitcher of *N. leonardoi* (Leonardo's Pitcher Plant).

At 1100 h on 23 September 2014, while examining pitcher contents of *N. leonardoi* at Shumkat Peak in Barangay Dumagueña, Narra Municipality, Palawan Province, Palawan Island, Philippines (9.472397°N, 118.383850°E, WGS84; 1365 m elev.), a deceased *P. albotaeniata* (SVL = 20 mm) was observed by EKT on its back inside a globose lower pitcher (Fig. 1A). The frog was fully intact (Fig. 1B) which suggests that it recently drowned in the viscous liquid inside the pitcher. To our knowledge, this is the first reported association of a Philippine frog with pitcher plants. Photographic vouchers were deposited at the Lee Kong Chian Natural History Museum, National University of Singapore (ZRC[IMG] 1.74 a–c).

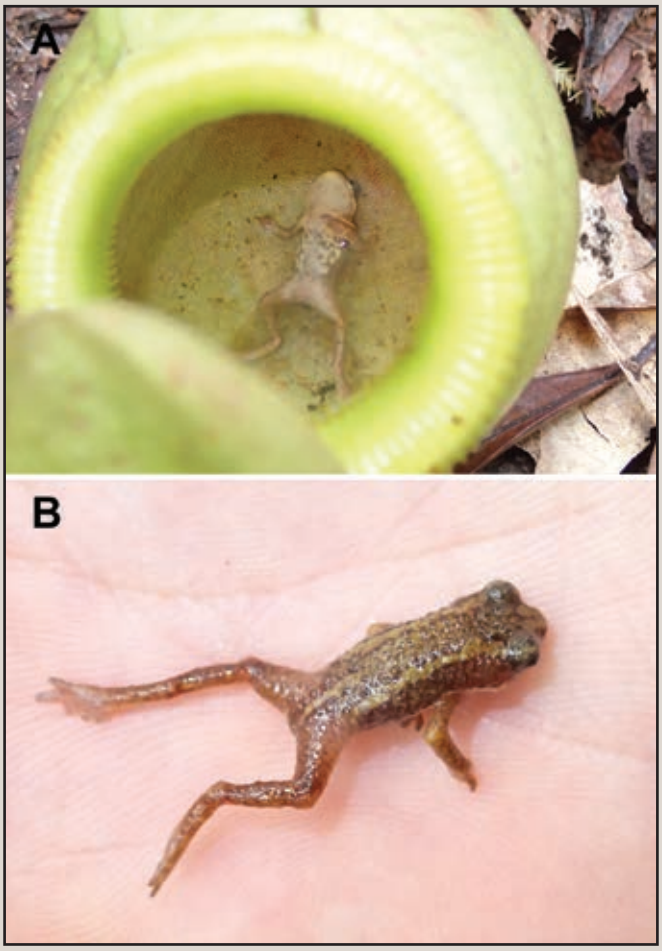

FIG. 1. A deceased *Pelophryne albotaeniata*. A) Inside a pitcher of *Nepenthes leonardoi*. B). Dorsal view of the deceased toadlet.

We thank Rafe Brown for confirming the identity of the frog, Masafumi Matsui for providing references, and Kelvin K. P. Lim for ZRC numbers for this note.

***RHINELLA CRUCIFER* (Striped Toad). OPPORTUNISTIC SCAVENGING.** Tadpoles are usually considered filter feeding herbivores, but there are some carnivorous species (Duellman and Trueb 1986. Biology of Amphibians. McGraw Hill, New York, New York. 577 pp.). Some tadpoles of the genus *Rhinella* are known to be benthic, inhabit lentic water, and feed on microorganisms (Wells 2007. The Ecology and Behavior of Amphibians. University of Chicago Press, Chicago, Illinois. 1400 pp.; Eterovick 2000. Copeia 2000:210–215). Nevertheless, the description of the tadpole of *Rhinella crucifer* is recent, and little is known about its biology (Ruas et al. 2012. Zootaxa 3299:66–68).

Here, we report an aggregation of *R. crucifer* tadpoles feeding from a carcass of an adult *Hypsiboas faber* (Smith Frog), in a permanent stream (Fig. 1). The event occurred on 30 November 2012 in a fragment of Atlantic Forest, located in Vale da Revolta on Parque Estadual dos Três Picos, municipality of Teresópolis, Rio de Janeiro state, Brazil (22.26000°S, 42.56000°W; "Córrego Alegre"). The frog carcass (ZUFRJ 12866) and one tadpole of the aggregation (ZUFRJ 12865) were captured as vouchers and deposited in the amphibian collection of the Zoology Department of the Universidade Federal do Rio de Janeiro (ZUFRJ).

The tadpole (total length = 20.8 mm; Gosner Stage 30) was identified as *R. crucifer* based on dental formula. The carcass was diaphanized following Taylor and Van Dyke 1985 (Cybium 9: 107–119), and identified as *Hypsiboas faber* based on comparison with a diaphanized specimen (UNIRIO 64) belonging to the herpetological collection of Universidade Federal do Estado do Rio de Janeiro (UNIRIO). To our knowledge, this is the first report of opportunistic scavenging by a tadpole upon an adult anuran. The event also improves the knowledge of the tadpole of *R. crucifer*.

***RHINELLA MARINA* (Cane Toad). INCIDENTAL TRANSLOCATION.** *Rhinella marina* has a native range spanning from the Amazon River Basin to southern Texas and has been successfully introduced to other U.S. states (Florida and Hawaii) and countries as a pest control measure at the peril of native diversity (Hero and Stoneham 2005. *In* Lannoo [ed.], Amphibian Declines: The Conservation Status of the United States Species, pp. 417–422. University of California Press, Berkeley, California. 1094 pp.).

On 11 January 2014, while shopping in the outdoor lawn and garden section of a home improvement store in Hattiesburg, Lamar Co., Mississippi, USA (31.32028°N, 89.37385°W; WGS84) we discovered a large female *R. marina* (SVL = 138 mm, 375.6 g) hopping between the aisles. Employees stated that this was not the first occurrence and that the toads would occasionally arrive within shipments of potted trees from nurseries based in Texas and Florida. We determined that the distributors in Texas were scattered around the Dallas area, far north of the known range of *R. marina* (Hero and Stoneham 2005, *op. cit.*). However, the company that shipped out of Florida has two nurseries on the southeast side of Lake Okeechobee, Palm Beach Co., where *R. marina* populations have been established from introductions since 1936 (Krakauer 1968. Herpetologica 24:214–221). Translocation via potted plants may also explain the rapid range expansion of Mediterranean Geckos (*Hemidactylus turcicus*) in Mississippi (Lee 2008. J. Mississippi Acad. Sci. 53:184–188). It is unclear how large the distribution network is for these nurseries and if *R. marina* can establish viable populations capable of overwintering in Mississippi, but this could lead to further introductions in Florida and portions of south Louisiana that have similar annual minimum temperatures.

AARON L. HOLBROOK, Department of Biological Sciences, University of Southern Mississippi, Hattiesburg, Mississippi 39406, USA; e-mail: aaron.holbrook@eagles.usm.edu.

***RHINELLA MARINA* (Cane Toad). SALINITY TOLERANCE.** *Rhinella marina*, formerly known as the Marine Toad, is in fact an inland/freshwater species native to Central and South America but has been successfully introduced throughout the world (Lever 2001. The Cane Toad: The History and Ecology of a Successful Colonist. Westbury Academic and Scientific Publishing, Otley, West Yorkshire. 230 pp.). Despite being a terrestrial species, it is also one of the few anurans thought to be able to tolerate high salinity levels. Existing evidence comes from laboratory experiments that show that adults can tolerate salinities of ~14‰ (40% seawater; Liggins and Grigg 1985. Comp. Biochem. Physiol. A: Mol. Integr. Physiol. 82:613–619), and field observations of adults in high salinity environments such as tidal flats, beaches, mangrove swamps, and even swimming in the ocean (reviewed in Lever 2001, *op. cit.)*.

Less is known, however, about the salinity tolerance of aquatic stages in the wild. Laboratory experiments have shown that *R. marina* eggs can tolerate salinity concentrations of ~5.4‰ (15% sea water; Ely 1944. Copeia 1944:256) but all tadpoles die within 3 h at salinities of 12‰ (Rios-López 2008. Amphibia-Reptilia 29:7–18); overall survival in the laboratory is limited to salinities below 8‰ (Rios-López 2008, *op. cit.*). Field observations have been more qualitative—even anecdotal. For instance, tadpoles of introduced populations of *R. marina* have been observed in saline environments where there is considerable influx of freshwater such as tidal flats or brackish marshes frequently inundated by rainwater (Pope 1917. Bull. Comp. Zool. 61:117–131; Wingate 1965. Herpetologica

FIG. 1. Tadpoles and toadlets of *Rhinella marina* in a high salinity mangrove lagoon in Playa Brava, Coiba Island, Panama.

21:202–218; Covaceich and Archer 1975. Mem. Queensland Mus. 17:305–310; Lever 2001, *op. cit.*). However, none of these studies have reported salinity estimates, making it difficult to infer levels of tolerance in the wild. Furthermore, a field survey of introduced populations of *R. marina* in Puerto Rico did not find larvae or tadpoles along a salinity gradient (Rios-López 2008, *op. cit.*). Therefore, it remains uncertain whether breeding is possible in highly saline water, and the extent to which aquatic stages can successfully develop in such water in the wild.

We here report a quantitative observation of tadpoles and toadlets of a native population of *R. marina* successfully living in a highly saline environment in the wild. On 20 February 2015 we observed a large number (probably thousands) of *R. marina* tadpoles (Fig. 1) and toadlets (Fig. 2) in a large mangrove lagoon (at least 100 m long; Fig. 3) at Playa Brava (7.5558°N, 81.8405°W; WGS 84) on Coiba Island, Panama (for video: https://www.youtube.com/watch?v=Bn6QQV1EqwY&feature=youtu.be). The lagoon was surrounded by tall (> 8 m) mangrove forest, and located ca. 200 m from the ocean and 100 m from the mouth of the Pozo River. Water salinity was 27.5‰ (YSI Professional Plus multiparameter water quality meter), within the standard range for brackish water (0.5–30‰). To our knowledge, this observation is the highest salinity concentration reported for living tadpoles and toadlets of *R. marina* in the wild. We also recorded temperature (29.5°C), dissolved oxygen (2.88 mg/L), pH (7.33), total dissolved solids (27537.50 mg/L), and specific conductance (42453 µS/cm).

Our observation is relevant for several reasons. First, islands often represent a challenge to colonization by amphibians (Duellman and Trueb 1986. Biology of Amphibians. McGraw-Hill, New York. 670 pp.). Coiba Island in particular possesses a rather depauperate amphibian community, with only five anuran species reported so far; of which *R. marina* is the most widespread and abundant (De la Riva 1997. *In* Castroviejo [ed.], Flora y Fauna del Parque Nacional de Coiba (Panamá), pp. 419–432. Agencia Española de Cooperación Internacional, Madrid). Our observation might therefore help explain the success of *R. marina* on Coiba Island, particularly in the dry season when freshwater is reduced. Finally, salinity represents a major physiological limit to amphibian life (Balinsky 1981. J. Exp. Zool. 215:335–350), and only a handful of species are known to tolerate high salinity levels in the wild (Viertel 1999. Amphibia-Reptilia 20:161–171; Liggins and Grigg 1985, *op.cit.*). A relevant example is *Fejervarya cancrivora* (Crab-Eating Frog)—considered the most salt tolerant species in the world—with adults (Uchiyama et al. 1990. Zool. Sci. 7:73–78) and tadpoles (Gordon et al. 1961. J. Exp. Biol. 38:659–678) able to withstand salinities of up to 33‰ and 35‰ in the wild, respectively. To the best of our knowledge, our observation in *R. marina* is also one of the highest salinity tolerance values for tadpoles and toadlets reported in nature, and so this species could provide a rare opportunity to explore the physiological mechanisms allowing such tolerance.

We thank C. Kelehear for assistance in identifying the toadlets from the photos, and for directing us to the relevant literature. D. Sharpe provided useful comments on an early version of the note, S. Mattson provided the photos herein, and A. Endara the video. Funding was provided by the Coiba-Bioblitz Expedition sponsored by the International League of Conservation Photographers. Additional support was provided by Sistema Nacional de Investigación (SNI) and Secretaría Nacional de Ciencia, Tecnología e Innovación (SENACYT), Panama.

***RULYRANA FLAVOPUNCTATA* (Yellow-spotted Cochran Frog). REPRODUCTION.** Though there is a strong phylogenetic signal in reproductive modes of amphibians (Gómez-Mestre et al. 2012. Evolution 66:3687–3700), if environmental conditions provide the opportunity, reproductive modes of amphibians may be plastic within a given species (Touchon and Warkentin 2008. Proc. Natl. Acad. Sci. USA 105:7495–7499; Toledo et al. 2012. J. Ethol. 30:331–336). On 26 December 2008, 01 March 2009, 10 December 2009, and 22 February 2010 we found egg clutches of the centrolenid frog *R. flavopunctata* on the limestone walls (Fig. 1) of the Cueva de los Tayos ("Cave of the Oilbirds," 32.1110°S, 77.7496°W, WGS84; 670 m elev.), in the Tayuntza River gorge, near Wisui Biological Station, Morona Santiago, Ecuador. Despite its name, it is not a real cave but an extremely narrow deep and dark gorge formed by the river (Fig. 2).

Rulyrana flavopunctata occurs along creeks at elevations between 300 and 1800 m on the Amazonian slopes of the Andes of Colombia and Ecuador (Lynch and Duellman 1973. Occ. Pap. Mus. Nat. Hist. 16:1–66; Castro et al. 2004. www.iucnredlist.org, accessed 18 Dec 2014). Most centrolenids are thought to lay their egg clutches on vegetation (Guayasamin et al. 2009. Zootaxa 2100:1–97). Very few centrolenids are known to lay eggs on rocks; exceptions include *Centrolene geckoideum* (Lynch et al. 1983. Stud. Neotrop. Fauna Environ. 18:239–243), *C. petrophilum* (Ruiz-Carranza and Lynch 1991. Lozania (Acta Zool. Colombiana) 58:1–26), and *Sachatamia albomaculata* (Puschendorf et al. 2004. Herpetol. Rev. 35:52). The egg clutches of other saxicolous glassfrogs, such as other species within *Rulyrana* or *Sachatamia*, have never been described, but in general centrolenid clutches are laid at male glassfrog calling sites (Cisneros-Heredia and McDiarmid 2007. Zootaxa 1572:1–82). In other areas (e.g., Cordillera de los Guacamayos in Ecuador), clutches of *R. flavopunctata* have been observed on vegetation, although these are not formally recorded in any literature (J. M. Guayasamin, pers. obs.). In contrast to the finding that *S. albomaculata* switches from vegetation to rocks at the onset of the dry season (Puschendorf et al. 2004, *op. cit.*) we found *R. flavopunctata* egg clutches on the rock walls during the rainy season.

A possible advantage of using this microhabitat for egg deposition is that these surfaces might be inaccessible to non-flying

predators (e.g., snakes, lizards, ants and other insects), as they would not have a good grip on these almost-vertical rocky surfaces. Conversely, rock may make it difficult for embryos to detect approaching predators through substrate vibration.

Microhabitat selection for egg clutches is critical to avoid dehydration or direct solar radiation. At Cueva de los Tayos, egg clutches were always found in dark and wet conditions (due to water spray), offering ideal conditions for the development of embryos. Our observations suggest that *R. flavopunctata* lay their eggs on the rock walls of the Tayuntza River gorge probably to reduce predator pressure, avoid direct sun light, and have constant humid conditions (which may allow them to extend their reproductive activity).

OCTAVIO JIMENEZ-ROBLES (e-mail: octavio.jimenez.robles@gmail.com), **IGNACIO DE LA RIVA**, Department of Biodiversity and Evolutionary Biology, Museo Nacional de Ciencias Naturales-CSIC, Madrid, Spain; **JUAN M. GUAYASAMIN**, Centro de Investigación de la Biodiversidad y el Cambio Climático (BioCamb), Universidad Tecnológica Indoamérica, Quito, Ecuador.

***SCINAX FUSCOVARIUS* (Snouted Treefrog). PREDATION.** *Scinax fuscovarius* is distributed over Southeastern Brazil, northern Argentina, Paraguay, and Bolivia (Dixo and Verdade 2006. Biota Neotrop. 6:1–20). *Leptodactylus latrans* (Criolla Frog) is widely

FIG. 1. *Leptodactylus latrans* preying upon *Scinax fuscovarius*.

distributed in tropical South America and east of the Andes (Ferreira and Tonini 2010. Herpetol. Notes 3:237–238). *Leptodactylus latrans* has a generalized diet, and several studies report anurans as a component of its diet (e.g., Solé et al. 2009. Herpetol. Notes 2:9–15); cannibalism is also reported (Teixeira and Vrcibradic 2003. Cuadernos Herpetol. 17:113–120). The predation of *Scinax fuscovarius* by *Leptodactylus latrans* (Fig. 1) was on 29 September 2013 in the municipality of Vassouras, in the state of Rio de Janeiro, Brazil (43.5233°S, 22.3041°W, WGS84). It occurred at the edge of a large pond, located in a pasture on a farm. *Scinax fuscovarius* was found emitting a distress call while trapped in the mouth of *L. latrans* (Fig. 1). After that, the *L. latrans* jumped into the pond, still holding the *S. fuscovarius*, and we could not see them anymore, although we could still hear the distress call. This is the first record of the genus *Scinax* as prey of *L. latrans*, improving the knowledge on the trophic interactions involving these two tropical anuran species.

We thank O. L. Peixoto for suggestions on the manuscript and R. Cable for revision of the manuscript.

ANDRESSA M. BEZERRA (e-mail: andressademellobezerra@gmail.com), **JOICE RUGGERI**, and **SERGIO P. CARVALHO-E-SILVA**, Laboratório de Anfíbios e Répteis, Instituto de Biologia, Universidade Federal do Rio de Janeiro, Ilha do Fundão, 21941-590, Rio de Janeiro, Rio de Janeiro, Brazil.

***SCINAX FUSCOVARIUS* (Snouted Treefrog). PREDATION.** *Scinax fuscovarius* is a treefrog widely distributed in Brazil, Paraguay, Bolivia, and northern Argentina (Haddad et al. 2013. Guide to the Amphibians of the Atlantic Forest: Diversity and Biology. São Paulo, Anolis Books. 547 pp.). This species is a known prey item for vertebrates and invertebrates (Furlan and Almeida 2010. Acta Sci. Biol. Sci. 32:121–124; Morais et al. 2013. Herpetol. Notes 6:567–568). The colubrid snake *Philodryas olfersii* (Green snake) has a wide distribution in South America (Leite et al. 2009. N. West. J. Zool. 5:53–60), occupying both open and forested areas (Hartmann and Marques 2005. Amphibia-Reptilia 26:25–31; Almeida and Santos 2011. Bol. Mus. Para. Emilio Goeldi Cienc.

FIG. 1. A) *Philodryas olfersii* immobilizing *Scinax fuscovarius*. B) *Philodryas olfersii* preying on a *Scinax fuscovarius*.

Nat. 6:351–354). On the night of 22 December 2012 in Angélica, Mato Grosso do Sul state, Midwest Brazil (22.1533°S, 53.7718°W, SAD-69), we observed a *P. olfersii* preying on a *S. fuscovarius* (Fig. 1). The *Scinax fuscovarius* was first attacked in the branches of a tree (3 m up), then both the frog and the snake dropped to the ground, where the struggle finished. The entire event lasted around 17 minutes, since the snake's first lunge until the frog was entirely swallowed. This is the first record of *P. olfersii* preying on *S. fuscovarius*; however the congener *P. patagoniensis* is a known predator of this frog (Hartmann and Marques 2005. Amphibia-Reptilia 26:25–31).

TESTUDINES — TURTLES

***CHELONIA MYDAS* (Green Sea Turtle). PREDATION.** The natural predation of adult sea turtles has received limited attention compared to the impacts of anthropogenic take. Recent reviews of predator-prey relationships (Whiting and Whiting 2011. Chelon. Conserv. Biol. 10:198–205; Heithaus 2013. *In* Wyneken et al. [eds.], The Biology of Sea Turtles, Volume 3, pp. 249–284. CRC Press, Boca Raton, Florida) listed several crocodilians including *Crocodylus acutus* (American Crocodile), *C. porosus* (Saltwater Crocodile), and *Alligator mississippiensis* (American Alligator) as responsible for predation events that involved *Lepidochelys olivacea* (Olive Ridley Sea Turtle), *Dermochelys coriacea* (Leatherback Sea Turtle), *Eretmochelys imbricata* (Hawksbill Sea Turtle), and *Natator depressus* (Flatback Sea Turtle) as prey (most often as hatchlings, but also the adults). However, there appear to be no published accounts of crocodilian predation on Green Sea Turtles (*Chelonia mydas*) in the literature.

Herein we report a documented predation of an adult *C. mydas* by a *Crocodylus porosus*). While boating at Winyalkin Island (14.459°S, 125.527°E) on 28 January 2014 on the Kimberley coast of Western Australia, AK photographed a Green Sea Turtle returning to the water after a nesting attempt. The species identification was clear from the characteristic parallel flipper tracks on the beach. A few moments after the turtle re-entered the water, a large crocodile surfaced near the shore with the captured turtle in its jaws. The crocodile paralleled the shoreline with the captured turtle and the boat steered nearer to continue observations and obtain digital photographs. The images, while not of sufficient resolution for publishing, allowed documentation of diagnostic Green Sea Turtle features, including scute or scale patterns of the head, front flipper and carapace, distinctive coloration, and head morphology. The crocodile and turtle prey were lost to sight as it left the area, so we cannot speculate about final consumption.

The fortuitous images provided no clearly-calibrated visual references for size. However, there are regional data sets that supply helpful estimators of relative prey and predator sizes. The mean size of Western Australia Green Sea Turtles (98.0 = cm curved carapace length, source: B. Prince- DPAW), and a 1:7–1:8 ratio for large *C. porosus* head to body length (Britton et al. 2012. Herpetol. Rev. 43:541–546; Fukuda et al. 2013. J. Herpetol. 47:34–40), allows a judicious guess that the crocodile involved was around 4–5 m in length.

***CHELYDRA SERPENTINA* (Snapping Turtle). INJURY.** Here we report an observation of a male *Chelydra serpentina* being wounded within a hoop trap. On 8 July 2014 at approximately 1120 h, while checking hoop traps baited with sardines, in Presqu'ile Provincial Park (43.994421°N, 77.720144°W), Ontario, Canada, we found that one hoop trap contained three adult *C. serpentina*: two males (M_1: SCL = 30.9 cm, mass = 7.55 kg; M_2: SCL = 23.4 cm, mass =3.55 kg) and one female (F_1: SCL = 28.2 cm, mass = 5.85 kg). This is not necessarily unexpected; Frazer et al. (1990 Copeia 1990:1150–1152) noted that the presence of a female in a hoop trap may artificially increase capture rates of males. Upon retrieval from the trap, a deep lengthwise tear through skin and muscle along M_1's tail was noted. The wound extended through the cloaca, and was approximately 10 cm in length (Fig. 1). The wound was fresh and still bleeding; neither scabbing nor scar tissue were present. Three explanations for the cause of the wound seem plausible: 1) M_1 was injured before entering the trap, 2) M_1 was attacked by one or both of the other turtles (M_2 and F_1) within the trap, or 3) while attempting to copulate with F_1, she scratched M_1's cloaca with her hind claw. Due to the wound's length, linear pattern, and lack of additional injuries on any of the turtles, we

PHOTO BY SEAN P. BOYLE

FIG. 1. Wound through the cloaca of a large male *Chelydra serpentina* (M_1) after being removed from a hoop trap with two other adult *C. serpentina* (M_2 and F_1).

believe the injury resulted from a struggle within the trap and that a claw was its likely source, potentially sustained while attempting to copulate with F_1. Given that increased body size is often correlated with dominance, both inter- and intra-sexually, in sexually dimorphic turtles (Berry and Shine 1980. Oecologia 44[2]:185–191), the fact that the injured turtle was also the largest, and the only one injured, further supports the conclusion that this injury was related to mating.

Before taking measurements, and before release, the wound was rinsed with water and the edges were cleaned with an alcohol swab. M_1 appeared to behave normally, and upon release, swam normally. Although M_1 was not recaptured again throughout the summer (capture rates decrease by late July at our study site), we do not believe that the wound observed would have led to a severe infection and subsequent mortality.

Male *C. serpentina* are known for intraspecific aggression towards females (White and Murphy 1973. Herpetologica 29:240–246) and males (Brooks and Brown 1983. Herpetologica 49:311–318) during the breeding season, but little is known about wounds caused by females. Male *C. serpentina* may behave aggressively to other males while within close proximity to females (Brooks and Brown 1983, *op. cit.*) and in combat, they have been observed biting and clawing at their opponent's head (Raney and Josephson 1954. Copeia 1954:228). Recent scars on the heads of *C. serpentina* can be seen each spring; however, direct observation of aggression in the wild is rare (Galbraith et al. 1987. Can. J. Zool. 65:2623–2629). To our knowledge, only one (unpublished) study has analyzed long-term wounding trends for *C. serpentina* (Hewitt 2014. Honours Thesis, Laurentian University, Sudbury, Ontario; Keevil, Hewitt, and Litzgus, unpubl.).

Given the known aggressive nature of *C. serpentina*, we believe aggression within hoop traps may be more common than the lack of published accounts suggests. Although hoop traps are a commonly-used technique for the capture of various freshwater turtle species, our observation is an important reminder that live-trapping has ethical significance related to stress or injury of both focal and by-catch species. We recommend, when possible, checking hoop traps frequently (more than once/day), in order to minimize the likelihood of such potentially damaging interactions.

Funding for this project was provided in part by Laurentian University, Presqu'ile Provincial Park, Ontario Ministry of Natural Resources and Forestry Species At Risk Stewardship Fund, and the Friends of Presqu'ile Provincial Park. We thank Matt Wheeler and Natasha Noble for field support, and Matthew Keevil for his helpful review.

***CHELYDRA SERPENTINA* (Snapping Turtle). HUNTING BEHAVIOR.** Snapping Turtles are large omnivorous freshwater turtles that are reported to both scavenge and actively hunt for prey (Ernst and Lovich 2009. Turtles of the United States and Canada, 2nd ed. John Hopkins University Press, Baltimore, Maryland. 827 pp.). Relatively large mammals (e.g., Muskrat, *Ondatra zibethicus*) have rarely been reported in gut-content analysis studies (Alexander 1943. J. Wildl. Manag. 7:278–282; Lager 1943. Am. Midl. Nat. 29:257–312), and these findings are usually attributed to scavenging. Only one prior report describes predation on a living *O. zibethicus* (Abbott 1884. A Naturalist's Rambles about Home. D. Appleton & Co., New York. 485 pp.). Predation of waterfowl is better documented in the literature, including predation on large Trumpeter Swan (*Cygnus buccinator*) cygnets (Abel 1992. The Passenger Pigeon 54:209–214). Here we document *C. serpentina* predation on a relatively large living mammal, the North American Porcupine (*Erethizon dorsatum*).

Starting at approx. 1208 h on 4 July 2013, Dana and Elaine Hilmer observed an adult *C. serpentina* capture and prey upon a living *E. dorsatum* while paddling along the Turtle Flambeau Flowage (46.102°N, 90.103°W) in northern Wisconsin. The observation started when they noticed a young *E. dorsatum* feeding along the shore in a small bay that had some floating dead tree trunks drifted up against the shore. Pictures and videos were taken as the *E. dorsatum* moved out over the water onto the logs. The *E. dorsatum* started browsing on a floating mat of water plants that were near the logs. The observers then noticed that something was bothering the animal's foot, and observed it start

PHOTO BY D. AND E. HILMER

FIG. 1. Snapping Turtle (*Chelydra serpentina*) hindlimb protruding out of the water during a struggle with a young North American Porcupine (*Erethizon dorsatum*).

to thrash around (Fig. 1). At first they thought the *E. dorsatum* had fallen off the floating vegetation, or that it was feeding on something in the water. However, after the *E. dorsatum* lay motionless in the water for a few minutes, both observers paddled closer to get a better view. At this point, they observed a large *C. serpentina* feeding on the *E. dorsatum*. The turtle had quills stuck into its neck and forelimbs following the struggle. From the photographs and video recorded during the encounter, it appears certain that the *C. serpentina* had dragged the *E. dorsatum* into the water and drowned it.

E. dorsatum is reported to have few natural predators (Feldhamer et al. 2003. Wild Mammals of North America: Biology, Management, and Economics. 2nd ed. Johns Hopkins University Press, Baltimore, Maryland. 1216 pp.), but this list must now include *C. serpentina*.

A video of this encounter can be viewed online by visiting http://youtu.be/WMbPIS5tulw. In addition, a copy of the video and supplemental photographs are accessioned in the James Ford Bell Museum of Natural History Herpetological Collection (JFBM P487). We thank Dana and Elaine Hilmer for sharing their video and story, and granting us permission to publish this observation.

***CHELYDRA SERPENTINA* (Snapping Turtle). BASKING HEIGHT.** Aquatic turtles employ aerial basking as a means of thermoregulation and possible epidermal parasite control (Boyer 1965. Ecology 46:99–118). In *Chelydra serpentina*, aerial basking behavior is generally uncommon (Ernst and Lovich 2009. Turtles of the United States and Canada, 2nd ed. Johns Hopkins Univ. Press, Baltimore, Maryland. 827 pp.). Published accounts documenting aerial basking in *C. serpentina* note that individuals utilize shorelines or low-lying rocks, logs, and stumps protruding slightly from the surface of the water as basking platforms (Obbard and Brooks 1979. Can. J. Zool. 57:435–440; Roble and Garriock 1998. Catesbeiana 18:53–54). Herein, I report an observation of an adult *C. serpentina* at an unusually high basking height.

On 23 May 2014, at ~1330 h, I observed an adult *C. serpentina* (visually estimated carapace length ~35 cm) basking in a wetlands area along the Bloomsburg Rail Trail, Bloomsburg, Pennsylvania, USA (41.007975°N, 76.463670°W, WGS84; elev. ~150 m). The individual was basking upon the trunk of a dead tree protruding at a low diagonal angle from a small pond. Notably, the turtle was located at a height of approximately 1 m above the surface of the water. When I approached for closer observation, the *C. serpentina* retreated into the water by means of a vertical plunge. Adult *C. serpentina* of comparable size to the individual observed herein have previously been reported at basking heights of ~0.25 m above the surface of water (Roble and Garriock 1998, *op. cit.*). Additionally, Roble and Garriock (1998, *op. cit.*) observed a young *C. serpentina* in North Carolina basking ~1.3 m above the surface of the water on a vertical stump; however, to my knowledge basking observations of similar height have not previously been reported in adult *C. serpentina*.

***CHELYDRA SERPENTINA* (Snapping Turtle), *CHRYSEMYS PICTA PICTA* (Eastern Painted Turtle), *STERNOTHERUS ODORATUS* (Eastern Musk Turtle), *TRACHEMYS SCRIPTA ELEGANS* (Red-eared Slider). URBAN POPULATION DENSITY.** We report notably high trapping success for turtles from an urban pond with minimal trapping effort (a single night of trapping and only eight traps). Our study took place at the southern pond of Beaver Pond Park (BPP; 2.67 ha surface area; 41.32737°N, 72.9399°W; New Haven, Connecticut, USA). From 1710 until the late 1800s, the pond was surrounded by cattle grazing. In 1885, a slaughterhouse dumped waste into the pond and from around 1894–1918 the pond was repeatedly filled with dirt, municipal waste, and cinder ash from the Winchester Repeating Arms factory (A. A. Doolittle, pers. comm.). Currently, the southern pond is immediately surrounded by suburban residential neighborhoods, a police firing range, and a high

FIG. 1. 2013 satellite image (ESRI World Imagery Basemap) of Beaver Pond Park (BPP) in New Haven, Connecticut. We studied the southern pond at BPP (indicated by a white arrow). Athletic fields abut the southern perimeter of the southern pond. The dominant landscape features around the pond are roads and residential neighborhoods.

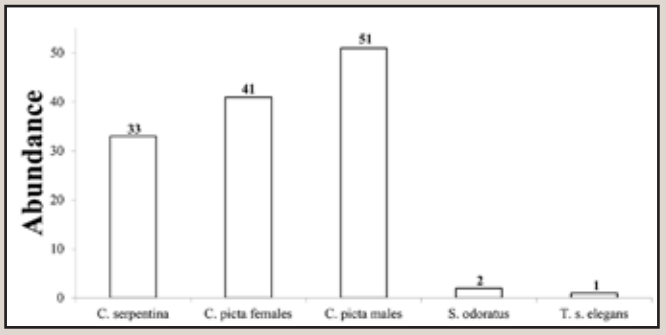

FIG. 2. The abundances of four turtle species caught in a single night with eight hoop net traps at the 2.67-ha southern pond at Beaver Pond Park. Numbers over bars are the total abundance for a given taxon.

school football field and track (Fig. 1). The park is maintained and managed both by the city of New Haven as well as the volunteer organization, Friends of Beaver Pond Park (FoBPP).

We set eight 1-m diameter hoop-net traps baited with frozen mackerel at 1030 h on 31 May 2012 and began checking traps on 01 June 2012 at 1000 h. Each trap was placed ~1 m offshore, parallel to the bank, and submerged with several centimeters of trap above water so turtles could breathe. We sexed all *Chrysemys p. picta* following Ernst and Lovich (2009. Turtles of the United States and Canada. 2nd edition. Johns Hopkins University Press, Baltimore, Maryland. 827 pp.) but did not sex other species. After marking, we immediately released each turtle back into the pond.

We caught 128 unique turtles overnight (species breakdown and abundance, Fig. 2). Abundances equate to densities of 34.5 *C. p. picta*/ha and 12.4 *Chelydra serpentina*/ha in a single night of trapping. For *C. picta*, the adult sex ratio did not deviate from equal proportions of males and females ($\chi^2 = 0.35$, $p = 0.55$).

Urbanization is usually associated with turtle declines (Garber and Burger 1995. Ecol. Appl. 5:1151–1162; Klemens 2000. Turtle Conservation. Smithsonian Inst. Press, Washington DC. 344 pp.) with road mortality (Gibbs and Steen 2005. Conserv. Biol. 19:552–556; Patrick and Gibbs 2010. Landscape Ecol. 25:791–801) and introduced *Trachemys scripta elegans* (Spinks et al. 2003. Biol. Conserv. 113:257–267; Lambert et al. 2013. Chelon. Conserv. Biol. 12:192–199) suggested as likely threats. Even so, urbanized waterbodies can support robust populations of some turtle species (Spinks et al., *op. cit.*; Lambert et al., *op. cit.*).

While our data were acquired from only a single night's trapping, the number of turtles caught is notable. Our data suggest a relatively robust community of native turtles at densities equal to or greater than those reported for other urban ponds (Steen and Gibbs 2004. Conserv. Biol. 18:1143–1148; Eskew et al. 2010. Chelon. Conserv. Biol. 9:244–249). High road density reportedly can cause male-biased sex ratios in urban turtle populations (Gibbs and Steen, *op. cit.*; Patrick and Gibbs, *op. cit.*), but our data do not indicate this effect at BPP. As *T. s. elegans* are often found in high density in urban environments, mostly as released pets (Spinks et al., *op. cit.*; Teillac-Deschamps et al. 2008. *In* Mitchell et al. [eds.], Urban Herpetology. Herpetological Conservation 3:535–537. Society for the Study of Amphibians and Reptiles, Salt Lake City, Utah; Lambert et al., *op. cit.*), we expected to trap numerous introduced turtles. However, we found only one *T. s. elegans* indicating that this urban pond is currently not impacted by introduced turtle species.

Urban ponds have been acknowledged as important arenas for freshwater turtle conservation (Spinks et al., *op. cit.*; Lambert et al., *op. cit.*). It is possible that the current level of robust park stewardship (e.g., FoBPP) and socio-economic dynamics of the community surrounding BPP are maintaining a healthy urban turtle population despite intense land use, both historical and contemporary. Our preliminary data indicate that future longitudinal studies of BPP turtle dynamics could be relevant for studies of urban turtle conservation.

We thank A. Bartow, K. Beitler, Hillhouse High School AP Environmental Studies and AP Biology students, V. & H. Lambert, J. Richardson, and P. Smith for their field assistance. We also thank A. A. Doolittle for discussions about the history of the Beaver Pond Park. The Yale School of Forestry and Environmental Studies Class of 1980 funded our traps and bait. This work was done under Yale IACUC 2012-10681, New Haven Parks, Recreation and Trees Permit 11352, and CT DEEP Permit 1213004.

***GLYPTEMYS INSCULPTA* (Wood Turtle). MORTALITY.** On 29 May 2013 at 1456 h in Kalkaska Co., Grayling, Michigan, USA (44.639594°N, 84.892294°W; datum WGS 84), we observed an adult *Glyptemys insculpta* in a sandy creek bed filled with water ca. 0.5 m deep. We subsequently observed two adult *Chelydra serpentina* (Snapping Turtles) ca. 3 m away on either side of the *G. insculpta*; one was resting in shrubs to the right and the other was to the left submerged.

At approximately 1100 h the following day, the *G. insculpta* was found dead underwater in the creek bed where it had previously been observed. Its head was largely missing, and most of the cervical vertebrae, as well as minimal amounts of muscle and connective tissue were still attached to the body. It appeared as if the head was "stripped" off. We compared photographs of markings on the *G. insculpta* from when it was alive to the carcass to confirm it was the same individual. The *C. serpentina* were not seen again. Due to the lack of any damage to the rest of the *G. insculpta* indicative of predation by a mammalian or avian predator, and because only chelonian tracks were observed in the sand in the area where the event took place, we assume it was killed by a *C. serpentina*.

We speculate that a *C. serpentina* seized the *G. insculpta*, killed it, and consumed most of the head. Punzo (1975. J. Herpetol. 9:207–210) documented unidentified chelonian shell fragments in stomach contents of *C. serpentina* and also noted they will actively pursue and consume larger prey by holding it in their mouths and shredding it with their front claws. However, we cannot be certain if this event represents intentional predation. While the creek bed in this observation was relatively small, it is also possible that a *C. serpentina* may have killed the *G. insculpta* out of aggression or territoriality.

SASHA J. TETZLAFF (e-mail: tetzsj01@ipfw.edu), and **MICHAEL J. RAVESI**, Department of Biology, Indiana University-Purdue University Fort Wayne, 2101 E. Coliseum Boulevard, Fort Wayne, Indiana 46805, USA.

***GLYPTEMYS INSCULPTA* (Wood Turtle). LONGEVITY IN THE WILD.** The previous published record for oldest male and female *G. insculpta* in the wild was 42 and 46 years old, respectively. Both individuals were from a population in Pennsylvania (Ernst 2001. Chelonian Conserv. Biol. 4:94–99). Here, we report 3 males and 22 females in Minnesota, USA, that exceed the published longevity records (specific locations withheld in compliance with state of Minnesota data practices law). Individuals were originally marked using carapace notches (Cagle 1939. Copeia 1939[3]:170–173) and aged using plastron annuli counts (Harding and Bloomer 1979. Herp: Bull. New York Herpetol. Soc. 15:9–26) between 1990 and 1993 by MDN and RRB. We consider the ages determined between 1990 and 1993 to be minimum ages, as the number of distinguishable annuli for the individuals included here was between 23 and 32, and annuli typically become more difficult to distinguish as *G. insculpta* age (Harding and Bloomer, *op. cit.*). The most recent capture of marked individuals occurred between 2012 and 2014 by MS, DR, and RAM. The oldest minimum-age male recaptured was 48 years old in 2013, and the oldest minimum-age female recaptured was 55 years old in 2014 (Table 1). Thus, our current female record in the wild is nearing the published record of 58 years for *G. insculpta* longevity in captivity (Oliver 1955. The Natural History of

TABLE 1. Minimum ages of *Glyptemys insculpta* in Minnesota, USA, that exceed the previous published longevity records of 42 years (male) and 46 years (female) in the wild. All records are from individuals alive at time of last capture.

***GOPHERUS POLYPHEMUS* (Gopher Tortoise). BURROW ASSOCIATE.** Gopher Tortoises are considered a keystone species due to their characteristic burrows; many vertebrate species temporarily occupy these burrows, including nearly all the venomous snakes found within the range of the tortoise (Jackson and Milstrey 1989. *In* Diemer et al. [eds], Proceedings of the Gopher Tortoise Relocation Symposium, pp. 86–98. Florida Game and Fresh Water Fish Commission, Tallahassee, Florida). However, *Agkistrodon contortrix* (Copperhead) has not previously been reported as a burrow associate of *G. polyphemus*. At 1530 h on 16 March 2015 we found an adult *A. contortrix* coiled within the entrance of an active *G. polyphemus* burrow within the Apalachicola Bluffs and Ravines Preserve in Liberty Co., Florida, USA (30.49399°N 84.98351°W; WGS 84). We did not confirm that the burrow was simultaneously occupied by a tortoise; however, the burrow had a well maintained entrance and fresh sand was visible on the apron. The snake appeared to be posed in the characteristic ambush posture of pitvipers (Fig. 1). That this is the first report of *A. contortrix* in the burrow of *G. polyphemus* is not entirely unexpected; the habitat preferences of these animals do not generally overlap. However, at this site, upland *Pinus palustris* (Longleaf Pine) and *Aristida stricta* (Wiregrass) habitats are immediately adjacent to mesic hardwood forests and bottomlands, potentially bringing both species in close proximity.

FIG. 1. *Agkistrodon contortrix* found within the burrow of a *Gopherus polyphemus* burrow in Liberty Co., Florida, USA.

***PODOCNEMIS EXPANSA* (Giant Amazon River Turtle). POST-REPRODUCTIVE MIGRATION.** *Podocnemis expansa* is a large herbivorous turtle that moves into inundated floodplains to feed during the rainy season. Here we provide preliminary data on the post-nesting movements of adult females in the Lower Xingu River, Amazon Basin, Brazil. Between 9 October and 5 November 2013, eight adult females were captured after completing their nests on Juncal Beach, Xingu River (2.706204°S, 52.022879°W, WGS 84). Satellite transmitters (UHF KiwiSat 101 PTT) were installed on the posterior margin of their shells using Turbolit epoxy. These individuals were then released after 24 hours, at the point of capture. Subsequent positions were recorded daily by the ARGOS (www.argos-system.org) satellites system and processed by CLS (Collecte Localisation Satellites, www.cls.fr). One individual was monitored for 143 days, five individuals for 320 days, and two other individuals were still transmitting signals at this writing. We identified three different routes of dispersion: 1) five females migrated to the Amazon estuary in the Delta Archipelago

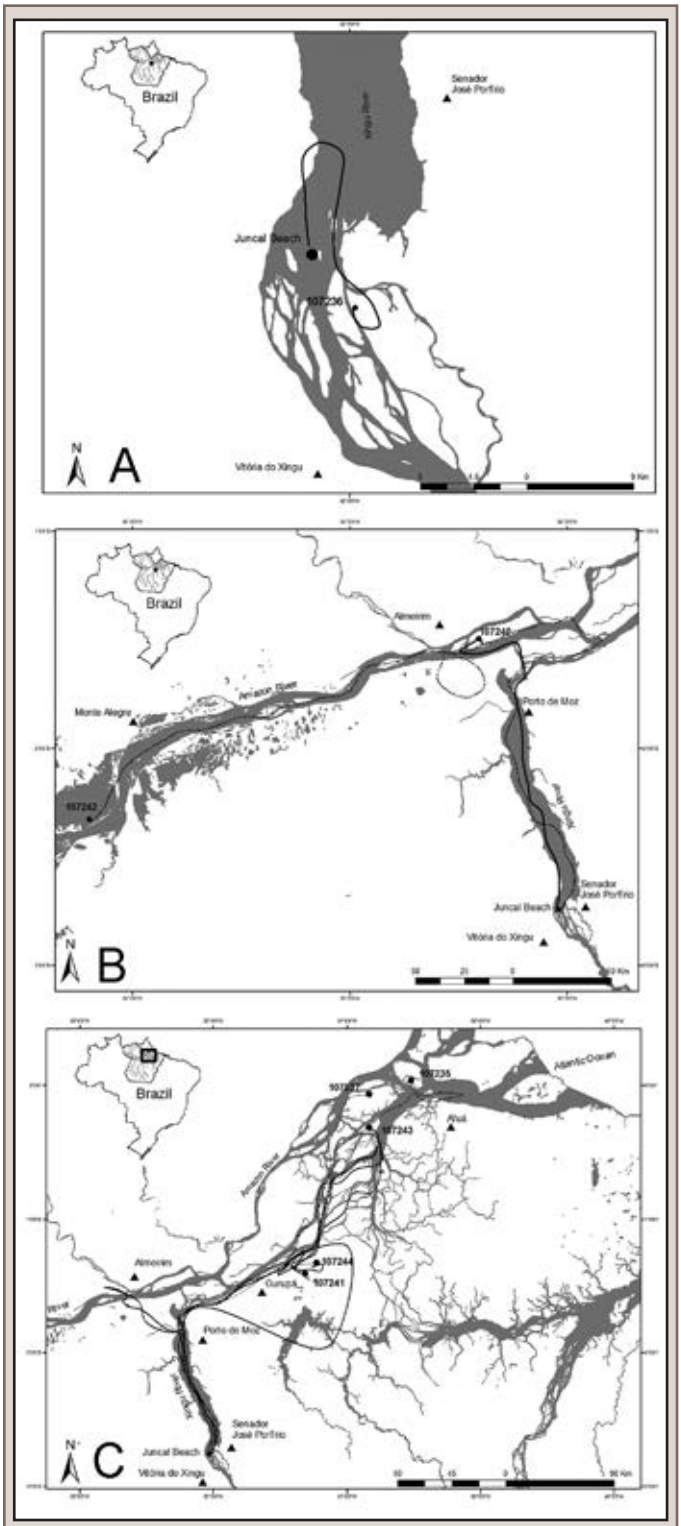

FIG. 1. Movement patterns of adult female *Podocnemis expansa* after nesting in the Juncal Beach: A) area used by one individual within the floodplains close to the nesting beach; B) route of one individual downstream Xingu River and then upstream Amazon River; C) route of six individuals downstream Xingu and Amazon Rivers to the Delta.

after swimming down the Xingu River; 2) two dispersed up the Amazon after swimming down the Xingu River; and 3) the last one stayed within the floodplains relatively close to the nesting beach (Fig. 1).

The average duration of uninterrupted movement from the nesting beaches to the feeding areas in the floodplain was 36.4 ± 20.59 days (9 – 81, N = 7), and the average distance travelled was 405.1 ± 114.7 km (196–725, N = 7). After the initial movements described above, all monitored individuals significantly reduced their movements and remained in the floodplains of the Lower Xingu River (N = 1), Lower Amazon (N = 2), or the Delta Archipelago (N = 5). These findings have important conservation implications, because almost all protective efforts are now restricted to the nesting beaches and surroundings. Conservation policy for Amazon River turtles, and especially for *Podocnemis expansa*, should consider the entire home range of the nesting populations. Considering the size of the area used by the turtles, and also the relatively high density of the human population along the river margins, it will be important to use innovative approaches to turtle conservation that include local communities.

CRISTIANE COSTA CARNEIRO (e-mail: criskbio@yahoo.com.br), and **JUAREZ PEZZUTI***, Universidade Federal do Pará, R. Augusto Correa 01, CEP 66075-110, Belém, Pará Brazil (e-mail: juca@ufpa.br). *Corresponding author.

***STERNOTHERUS ODORATUS* (Eastern Musk Turtle). HOME RANGE.** *Sternotherus odoratus* is a small, highly aquatic freshwater turtle, ranging from the southeastern United States north into the Canadian provinces of Ontario and Quebec (Ernst and Lovich 2009. Turtles of the United States and Canada. The Johns Hopkins Univ. Press, Baltimore, Maryland. 827 pp.).

We surveyed for species-at-risk turtles on the Trent Severn Waterway in Ontario, Canada, from Peterborough (44.3°N, 78.3°W; WGS84) to Trenton (44.1°N, 77.6°W), from May 2007 to May 2009. During this time, we captured and marked 86 *S. odoratus* (51 adult males, 31 adult females, and 4 juveniles). We attached VHF transmitters to four adult turtles (2 males, 2 females) in the Otonabee River (44.16° N, 78.236° W) in the spring and summer of 2008, and radio-located them approximately once per week until September 2008. We calculated home range size as the minimum convex polygon (100% MCP) and home range length (shortest straight line distance between two farthest locations). We also calculated an average daily distance moved as the mean straight line distance between two consecutive locations, divided by the number of days between them. Home range size calculations for *S. odoratus* ideally remove terrestrial habitat from their estimates (e.g., Picard, Carrière, and Blouin-Demers 2011. Amphibia-Reptilia 32:83–92). Thus we removed terrestrial area (not classified as water or wetland in the 1:10000 Ontario Base Map) from MCPs and recalculated area. Results were as follows:

Female (150.643): Followed from 5 June–28 August 2008 (N = 17 locations). Mass = 231 g, midline carapace length = 10.58 cm. Home range: 100% MCP = 17.2 ha, MCP - land = 15.8 ha, length = 657.9 m. Average daily distance moved (range) = 37.0 m (range: 0–121.5 m/day).

Female (151.802): Followed from 10 May–28 August 2008 (N = 22 locations). Mass = 219 g, midline carapace length = 11.50 cm. Home range: 100% MCP = 35.6 ha, MCP - land = 35.2 ha, length = 1529.2 m. Average daily distance moved (range) = 42.2 m (range: 0.8–352.9 m/day)

Male (150.663): Followed from 27 May–26 August 2008 (N = 15 locations). Mass = 216 g, midline carapace length = 11.65 cm. Home range: 100% MCP = 430.1 ha, MCP - land = 204.9 ha, length = 5643.5 m. Average daily distance moved (range) = 84.5 m (range: 0.9–702.6 m/day)

Male (151.813): Followed from 10 May–26 August 2008 (N = 21 locations). Mass = 171 g, midline carapace length = 10.33 cm. Home range: 100% MCP = 7.6 ha, MCP - land = 6.8 ha, length = 332.4 m. Average daily distance moved (range) = 17.9 m (range: 0.6–68.5 m/day)

Male 150.663 has the largest home range size yet reported for *S. odoratus.* This turtle was originally caught in a wetland bordering the Otonabee River in late May 2008. He remained in this area throughout June, then moved across the river into a large side channel wetland in July. In August, he moved over 5 km towards the mouth of the Otonabee River at Rice Lake, presumably where he hibernated (he was located there in October and November 2008). We lost track of this turtle over the winter of 2008, so do not know if these movements represent an annual migration, or if this was directional dispersal to a new site.

Although long distance (> 1 km) movements of *S. odoratus* do not appear to be the norm, Edmonds (1998. M.Sc. Thesis, University of Guelph) reported a similar maximum male home range size of approximately 430 ha. We note, however, that this estimate included terrestrial and deep-water areas the turtle was unlikely to use. The estimated usable habitat area was estimated at 22.2 ha for this home range in Georgian Bay, Ontario (Edmonds 1998, *op. cit.*). Belleau (2008. M.Sc. Thesis, McGill University) reported a maximum average daily movement of 1000 m for *S. odoratus* in Norway Bay, Quebec. Indeed, home range size for *S. odoratus* appears to increase with latitude. Mean 100% MCP ranges from 0.94 ha (females) and 1.75 ha (males) in southeastern Pennsylvania (Ernst 1986. J. Herpetol. 20:341–352) to 48.89 ha (females) and 155.36 ha (males) in Georgian Bay, Ontario, Canada (Edmonds 1998, *op. cit.*). A later study in Georgian Bay, which excluded terrestrial habitat from home range estimates (100% MCP), found a maximum home range size of 205 ha, strikingly similar to our male 150.663, though in this case the turtle was a female *S. odoratus* (Laverty 2010. M.Sc. Thesis, Laurentian University). There are relatively few studies of the movement patterns of this species, thus further investigation into their spatial ecology across their range is necessary for interpretation of the biological relevance of variation in home range size along a latitudinal gradient.

AMANDA M. BENNETT (e-mail: abenne03@gmail.com), **MATTHEW G. KEEVIL**, and **JACQUELINE D. LITZGUS**, Department of Biology, Laurentian University, 935 Ramsey Lake Road, Sudbury, Ontario, Canada.

***TRACHEMYS SCRIPTA ELEGANS* (Red-eared Slider). MORTALITY.** Human-caused mortality for *Trachemys scripta elegans* has included being shot while basking, beheaded by fishermen after being hooked, killed by automotive traffic, and trapped for research and teaching purposes, and the pet and food industries (Ernst and Lovich. 2009. Turtles of the United States and Canada, 2nd ed. Johns Hopkins University Press, Baltimore, Maryland. 827 pp.). This report adds an additional anthropogenic hazard. On 18 May 2009 at 1300 h in Comanche Co., Texas, USA, on Hwy 16 ca. 1.39 mi. S of County Road 2156 (32.193400°N, 98.532396°W; 387 m elev.), an adult female *T. scripta* was found trapped in a cattle guard. The turtle was caught in a vertical position, face down between two of the rails at the bottom of the cattle guard. Both the anterior portion of the carapace and plastron were stuck between the rails (Fig. 1). It is likely that this specimen would have died had it not been discovered. Directly beneath the aforementioned specimen were the skeletal remains of another *T. s. elegans*. However, it is uncertain if this death was caused by a similar circumstance.

FIG. 1. Female *Trachemys scripta elegans* trapped in a cattle guard, Comanche Co., Texas.

The live specimen was photographed as found (UTA DC 8086) and then released. The dead specimen was also photographed (UTA DC 8087).

CROCODYLIA — CROCODILIANS

***ALLIGATOR MISSISSIPPIENSIS* (American Alligator). NECROTIZING EXFOLIATION.** Effects of a prior severe winter freeze on *Alligator mississippiensis* in Louisiana were documented (Joanen and McNease 1990. Proceedings of the 9th Working Meeting of the Crocodile Specialist Group, IUCN – The World Conservation Union, Gland, Switzerland. Volume 2. pp. 21–32) and behavioral responses to freezing have been described (Hagan et al. 1983. J. Herpetol. 17:402–404; Brandt and Mazzotti 1990. Copeia 1990:867–871). Captive *Crocodylus niloticus* (Nile Crocodiles) can develop "winter sores" when held under cold conditions, wherein blood supply to the skin is reduced and the action of the immune system is impeded, causing erosions between scales (Huchzermeyer 2002. Rev. Sci. Tech. Off. Int. Epiz. 21[2]:265–276). We recently observed a large free-ranging *A. mississippiensis* with necrotizing scale exfoliation possibly due to severe winter weather.

On 24 March 2014 (ca. 1745 h), RME observed an adult alligator that appeared listless on a bank of a canal near the headquarters of Rockefeller Wildlife Refuge (RWR) in Grand Chenier,

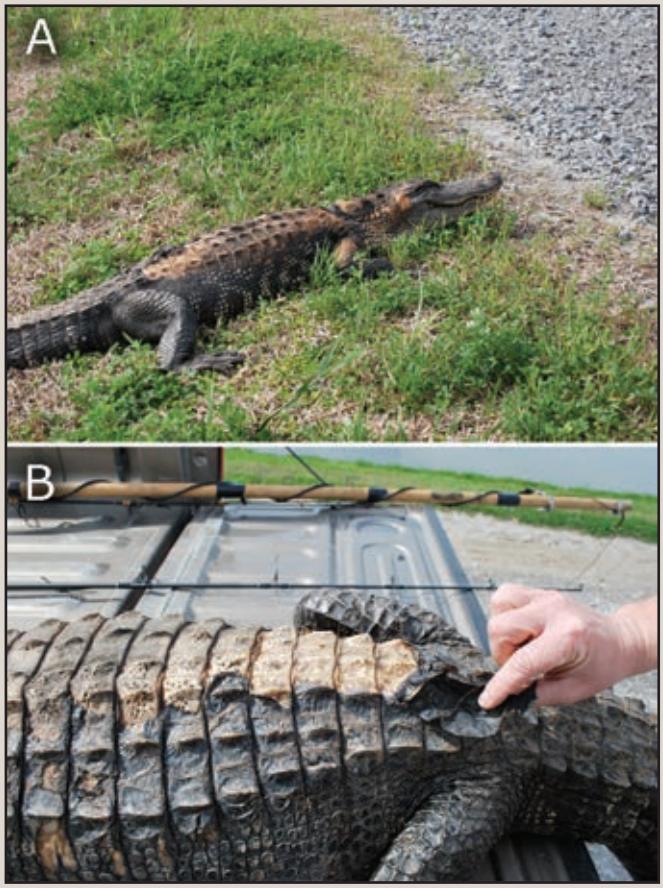

FIG. 1. Adult American Alligator (*Alligator mississippiensis*) immediately upon capture with necrotizing exfoliation (A) and detail of sloughing skin (B).

Louisiana, USA. The skin on the dorsal surface of the alligator was peeling off in numerous locations. Initially it was thought the alligator might be dead; upon gentle provocation it was guided back into the canal. The following morning (ca. 0930 h) the alligator was again observed in the water in nearly the same location. The alligator was readily observed even after submerging, as the exposed white osteoderms were visible as the overlying skin had been lost. After gathering equipment, the alligator was easily caught on the opposite bank of the canal. It did have strength to struggle mildly after capture, but less vigorously than normal for an alligator of comparable size. The male alligator was 239 cm total length, and had skin sloughing off the dorsal surface of the body (Fig. 1), including the head, neck, back, and limbs. The left rear foot had a prior well-healed amputation; likely due to trauma. The right eye was cloudy; when we tried to closely examine the left eye the surrounding skin sloughed off to mild touch. Several biopsies were taken of the skin surface. The animal was placed in a holding tank temporarily, but it was decided the alligator was near death and humane euthanasia was the best option. Arrangements were made for transport and full necropsy to be done at the Louisiana State University School of Veterinary Medicine.

At necropsy, a definitive cause of the condition could not be determined, but multiple abnormalities related to the necrotizing dermatitis and chronic debilitation were described, such as multisystemic thrombosis of small vessels possibly resulting from severe systemic inflammation and/or sepsis. The ulcerated dermis was colonized by moderate numbers of bacteria and fungal hyphae, which extended into the deep dermis, and there was some evidence of a non-severe pneumonia. The lesion in the right eye was thought to be chronic and unlikely to have contributed to the presenting condition. West Nile Virus testing was negative.

We suspect the alligator may have been adversely affected by numerous unusual regional winter freezes. The necrotic areas of the skin were on the surfaces that would have been in contact at the air-water interface for an alligator floating at the water surface. RWR documented three days of below-freezing temperatures from 6–8 January, with -6.67ºC (20ºF) on 7 January. For the ten day period from 22–31 January, nine days had temperatures at or below freezing, including -4.44ºC on 30 January; such extremes are rare in coastal Louisiana with three winter storms (i.e., ice and freezing rain) impacting the region within one month. In February 2014 another four days were at or below freezing, as well as similar freezing temperatures again on 4–5 March.

An adult alligator with similar dermatological abnormalities was observed on nearby private wetlands by RME on 16 December 2010. Temperatures at that time were not nearly as severe as in the present case, but there were six days with temperatures at/below freezing from 1–14 December, with the lowest temperature being -1.67ºC. At the time it was believed the skin lesions might be due to exposure to an environmental irritant or contaminant such as gasoline, or possibly the alligator may have been exposed to a controlled fire in a prescribed autumn/winter burn, which is a common marsh management tool. Indeed, similar skin sloughing was noted in a Saltwater Crocodile (*Crocodylus porosus*) trapped in a bushfire (Webb and Manolis 1989. Crocodiles of Australia. Reed Books Pty. Ltd.).

Deep hypothermia used for anesthesia in alligators caused local sloughing of the stratum corneum where scales were frozen (Kennedy and Brockman 1965. Herpetologica 21:6–15). Necrotic dermatitis and lifting of entire scales was also noted in a juvenile *C. porosus* that had been listless, not eating, and died of a generalized bacterial infection (Buenviaje et al. 1998. Aust. Vet. J. 76:357–363). Frye (1991. Biomedical and Surgical Aspects of Captive Reptile Husbandry. Vol. 1. Krieger Publishing Co. Malabar, Florida) discussed frostbite in reptiles, and noted severe hypothermic injury can cause tissue necrosis and dry gangrene.

Recent studies have shown that the blood of American Alligators has antibacterial (Merchant et al. 2003. Comp. Biochem. Physiol. 136:505–513), amoebacidal (Merchant et al. 2004. J. Parasitol. 90:1480–1483), and antiviral properties (Merchant et al. 2005. Antiviral Res. 66:35–38). However, natural mortalities do occur. To our knowledge, this is one of the rare instances of a wild crocodilian suffering exposure to ice storms and freezing temperatures, which may have been a contributing factor in its debilitated condition. It would be of interest to know how long it may have survived had we not elected to humanely euthanize it. It may be that wild alligators do succumb to extreme weather events, but after death in the wild, carcasses may rapidly deteriorate and are not known or recovered by researchers. It is possible that environmental stressors such as recent hurricanes in Louisiana followed by drought years might suppress the immune system and predispose some alligators to development of abnormal lesions or skin disorders. Additional research investigating such disease mechanisms in valuable crocodilian resources might be warranted.

***CROCODYLUS POROSUS* (Estuarine Crocodile). FISHING BEHAVIOR.** In all extant crocodilians, the morphology of the skull and feeding structures are strongly linked to the overall dietary preference and niche of a species (Pierce et al. 2008, J. Morphol. 269:840–864). In the case of *Crocodylus porosus*, the species is considered to be a generalist but its diet is dependent on the size of the animal. As a neonate the diet is comprised mainly of insects and other small compliant prey (Webb et al. 1991. J. Herpetol. 25:462–473). Sub-adults consume more robust prey such as birds, fish, small mammals, and carrion (Taylor 1979. Aust. Wild. Res. 6:347–359). Adult *C. porosus* are reportedly large game specialists consuming medium to large mammals and turtles (Webb and Manolis 1989. Australian Crocodiles, Reed Books Pty. Ltd, Sydney; Doody et al. 2009. Herpetol. Rev. 40:26–29). Although the diets of juveniles and sub-adults have been quantified for some areas (see Taylor 1979, *op. cit.*; Webb et al. 1991, *op. cit.*; Shahrul and Stuebing 1996. J. Trop. Ecol. 12:651–662), the diet, hunting strategies, and prey preferences of adults are limited to anecdotal observations and the occasional stomach sample. Recent observations by Britton and Britton (2013. Herpetol. Rev. 44:312) provided the first insight into the use of a unique foraging technique by *C. porosus* that was previously only recorded in *Caiman yacare* (Olmos and Sazima 1990. Copeia 1990:875–877) and *Caiman crocodilus* (Thorbjarnarson 1993. Copeia 1993:1166–1171). Here, we present three additional observations of cross-posture fishing by *C. porosus* and discuss the implications of these observations in terms of understanding the foraging strategies of the species in northern Australia.

On 24 April 2013, a *C. porosus* (total length ~150 cm) was observed in the Hunter River in the north Kimberley region of Western Australia. The *C. porosus* was observed to be herding prey items using the cross-posture fishing foraging technique in a small tributary of the river on the run out tide (Figs. 1–2). The *C. porosus* was observed with its front legs held perpendicular to the body, palms facing outwards and the toes projected above the water. Consistent with the observations of Britton and Britton (*op. cit.*) the jaws were held partially open with the upper jaw positioned just above the surface of the water and the lower just beneath. The *C. porosus* was observed lunging at mudskippers (*Oxudercinae* sp.) and prawns on the exposed mudflats. Occasionally, the animal was observed to lift its tail out of the water, which was thought to be a mechanism to stop prey from escaping the inlet.

On 2 March 2014, two adult *C. porosus* (total length ~ 250 cm and ~430 cm) were observed on the Yellow Waters Billabong region of the South Alligator River in Kakadu National Park, Northern Territory of Australia. Both animals were observed using the same cross-posture fishing technique. Both *C. porosus* were observed at a

FIG. 1. *Crocodylus porosus* using the cross-foraging posture in the Hunter River in the Kimberley region of Western Australia.

PHOTO BY GREG CALVERT

FIG. 2. Successful use of the cross-foraging posture by *Crocodylus porosus* to capture prey items in the Hunter River in the Kimberley region of Western Australia.

junction locally known as "three ways," which is situated on one of the upper freshwater billabong reaches of the South Alligator River. Despite observing the foraging activity for an hour, neither *C. porosus* was successful in capturing any prey items. It was noted that Ox-eye Herring (*Megalops cyprinoides*) were observed splashing on the surface in the vicinity of the observation. While we suspect that the individuals were targeting this prey item, this could not be confirmed given the lack of observations of successful prey capture.

A further observation was made on 16 May 2014, where an adult *C. porosus* (400–450 cm) was observed with arms outstretched in the Corroboree Billabong within the Mary River Region of the Northern Territory. While the individual was not observed to have caught any prey using this method, it is likely that the individual was also targeting Ox-eye Herring, a locally common fish species and which were observed splashing on the surface at the time near the observation. Ox-eye Herring have been observed to be a frequent prey item of *C. porosus* in this location previously (D. Rhind, pers. obs.). Although the cross-posture fishing technique has been documented previously (Britton and Britton, *op. cit.*), our observations confirm that the technique is not restricted to Cahill's

Crossing in Kakadu National Park and that the species uses this technique in both estuarine and freshwater systems, which are likely to have varying densities of prey. Our observations provides the first evidence of *C. porosus* using the technique to catch prey in freshwater systems in Australia as well as suggesting that this behavior might be more widespread across its range. Unfortunately, we are unable to determine whether these observations are site specific and we cannot rule out the possibility that the animals in the Mary and South Alligator River do not occasionally migrate to the East Alligator River during periods of high prey availability to use this technique. Our observations of this behavior in the Kimberley region confirm that *C. porosus* outside the Top End region of Northern Australia also use the technique when hunting fish. We propose that this behavior is likely to occur across the distribution of *C. porosus*, however further observations would confirm whether this is the case. Through the documentation of hunting behavior in *C. porosus*, it might be possible to better define the dietary preferences of adults as well as identifying the strategies used and quantifying the rate of hunting success.

***PALEOSUCHUS TRIGONATUS* (Schneider's Smooth-fronted Caiman). FEEDING BEHAVIOR.** *Paleosuchus trigonatus* is a small crocodilian species that primarily inhabits the closed canopy streams and smaller tributaries of the Amazon Basin (Magnuson and Lima 1991. Herpetol. Rev. 25:41–48; Campbell 1973. Herpetol. Rev. 7:318–320). Similar to other crocodilians, the diet includes a range of both terrestrial and aquatic vertebrates, and invertebrates. The diet of young *P. trigonatus* (SVL ca. 15.0–20.0 cm) is similar to that of the adults (Magnusson et al. 1987. J. Herpetol. 21:85–95). Predation events on *Bufo marinus* (Cane Toads) and *Caecilia marcusi* (Marcus' Caecilians) have also been reported (de Assis and dos Santos 2007. Herpetol. Rev. 38:445; Sampaio et al. 2013. Salamandra 49:227–228). Although the diet of this species has been studied, little is known of the foraging and feeding behavior of young *P. trigonatus*. We report here feeding events of juvenile caiman on two aquatic vertebrates and an invertebrate.

During an eight-month study on the ecology of *P. trigonatus* three observations were made of the feeding behavior of juvenile individuals at two research sites located on the Las Piedras River in the Madre de Dios department of southeastern Peru. During the study, individual caiman were tagged using passive induced transponders; transponder signals confirmed the caiman from these three observations as different individuals.

The first observation was made at 2108 h on 9 May 2013 in a shallow, fast-flowing forest stream at the Amazon Research and Conservation Center (12.04734°S, 69.68180°W, WGS84; 236 m elev.). The individual (SVL = 15.5 cm; tail length = 16.0 cm; 95.0 g) was found in rapids approximately 0.30 m from the bank in a hard-clay pool at a depth of 11 cm. The caiman was beside a submerged log masticating a moth approximately 5.0 cm in length. Upon capture the caiman opened its jaws in display, resulting in the moth dropping from the mouth.

The second observation occurred at 1811 h on 12 May 2013, approximately 40 m upstream from the first observation (12.04702°S, 69.68181°W; 240 m elev.). This individual (SVL = 16.0 cm; tail length = 13.0 cm; 91.0 g) was found in a shallow hard-clay pool one meter from the stream's primary channel. The pool was approximately 100 cm across and 50 cm in width with an approximate depth of 12 cm. The caiman was observed eating a fish that had a total length of 11 cm and weighed 20.2 g. Within one minute after we released the caiman, it retrieved the fish; however, we did not observe the caiman consume it.

The third observation was at 0154 h on 1 August 2013 in a stream at the Las Piedras Biodiversity Station (12.07285°S, 69.52499°W; 260 m elev.). The individual (SVL = 17.1; tail length = 16.6; 140 g) was found next to the bank under overhanging green vegetation in clear water with a sandy bottom at a depth of 22 cm. The individual had a *Helicops angulatus* (Brown-banded Water Snake) (SVL = 18 cm) firmly gripped mid-body. When first found, the snake was still alive and the caiman was using the support of a submerged branch. The caiman raised its head above the water and chewed twice before submerging its jaw with the snake under the water. The snake continuously thrashed as the caiman held it slightly submerged under the water. Over the course of two minutes the snake was observed to bite the caiman four times. However the caiman appeared unharmed by the defense. Approximately three minutes following the final defensive strike the caiman swam a distance of approximately one meter upstream with the snake still clutched in its jaws. It then retreated under a bank where it was captured for analysis. Upon capture the snake was found to be dead and despite being submerged in fast-flowing water the musk of the snake could be smelled emanating off of both individuals. During release the caiman was placed with the snake on the bank, however it quickly retreated beneath the opposite bank and out of site.

These observations further demonstrate the diverse prey base of this species and include insights into the feeding behavior of young individuals.

We thank Acadia University for funding and resources, the interns and volunteers at Fauna Forever who assisted during these observations, and special thanks to Brian Cnrobrna for guidance and support in the field.

PATRICK CHAMPAGNE (e-mail: 108291c@acadiau.ca), **STEVE MOCKFORD**, Acadia University, Wolfville, Nova Scotia, Canada, B4P 2R6; **CHRIS KIRKBY**, Fauna Forever, Carretera Tambopata Km 1.5, Puerto Maldonado, Peru.

SQUAMATA — LIZARDS

***AMEIVA EXSUL* (Puerto Rican Ground Lizard). REPRODUCTION.** *Ameiva exsul* is an abundant lizard distributed throughout Puerto Rico, the United States Virgin Islands, and the British Virgin Islands. It was recently introduced to St. Croix, which was a separate land bank that never hosted the species historically (Treglia et al. 2013. Carib. J. Sci. 47:360–365). This diurnal species occupies coastal forests and moves between shade and sun constantly. Lizards from different populations thermoregulate to different optimal temperatures. Eight lizards averaged a body temperature of 39.5 ± 1.42°C in Rosario Poblado, Puerto Rico (Rivera-Vélez and Lewis 1994. J. Herpetol. 28:1–6), while 89 lizards averaged a body temperature of 37.73 ± 0.23°C at the time of capture by noosing in Guana Island, British Virgin Islands (Gifford et al. 2012. J. Therm. Biol. 37:496–501). Females are rarely included in these studies due to low capture rates. The effect of thermoregulatory behavior on reproduction patterns in this species is largely unknown. Individuals reproduce discontinuously in southwestern Puerto Rico, presumably due to environmental

FIG. 1. Five eggs from a female *Ameiva exsul* in St. Croix, USVI.

TABLE. 1. Measurements of five eggs for an *Ameiva exsul* clutch oviposited in St. Croix, USVI.

Egg	Mass (g)	Length (mm)	Width (mm)	Diameter (mm)
1	1.2	18.83	10.77	34.07
2	1.2	17.91	10.14	36.13
3	1.2	18.51	10.99	35.63
4	1.1	18.72	10.41	33.11
5	1.1	17.81	10.11	33.56

cues (Rodriguez-Ramirez and Lewis 1991. Herpetologica 47:395–403). Rodriguez-Ramirez and Lewis (*op. cit.*) examined seven adult female *A. exsul,* which contained one to three oviductal eggs. An additional 18 adult females contained one to six enlarged follicles. Reports of clutches greater than three eggs are unknown, and the cloacal temperatures of a thermoregulating gravid females have not been published.

We captured a shuttling female *A. exsul* by noosing in St. Croix, United States Virgin Islands at 1228 h on 21 July 2014. At the time of capture, we read a cloacal temperature of 31.8°C. The cloacal temperature was below the temperature range of five male lizards that we caught from the same population (mean = 37.16°C, range: 36.3–38.4°C), so we measured the lizard's temperature again at the capture location while the lizard was unrestrained inside a pillowcase to check for accuracy. The second cloacal temperature reading was 31.8°C. At the time of capture, the lizard weighed 42.5 g, and we measured the following morphometric characters: SVL = 101.0 mm, tail length = 273 mm (no regeneration). The lizard was kept alone in a pillowcase overnight. On 22 July 2014, we prepared to take photographs of the lizard at 0830 h. After opening the bag and removing the female, we noticed several eggs in the bottom of the bag. We removed the eggs from the bag (Fig. 1) and external egg dimensions and mass were obtained (Table 1). The eggs were preserved in ethyl alcohol and deposited at the Texas A&M University Biodiversity Research and Teaching Collections.

Clutch size is known to vary among latitudes, seasons, and in response to local conditions (Shine 2005. Annu. Rev. Ecol. Evol. Syst. 36:23–46). In some species of lizards, only older and larger females produce large clutches. Large clutch size could indicate that the introduced population of ground lizards on St. Croix has responded to novel local conditions or that females live longer in St. Croix in the absence of native predators (i.e., predatory snakes are extinct in St. Croix). All of the eggs were viable; to our knowledge this is the largest egg clutch reported for the species. We suggest that this female *A. exsul* oviposited eggs voluntarily as a stress response. We believe that the female was maintaining a cooler body temperature at the time of capture than is normally associated with the species, perhaps for the benefit of the clutch.

NICOLE FRANCES ANGELI, Department of Wildlife and Fisheries Sciences, Texas A&M University, College Station, Texas 77843-2258, USA (e-mail: nangeli@tamu.edu); **KRISTINA CHYN** (e-mail: kchyn@tamu.com); **KAYCEE FAUNCE** (e-mail: kfaunce@mail.umw.edu).

***ANOLIS CAROLINENSIS* (Green Anole). DIET.** On 6 Aug 2014 an adult male *Anolis carolinensis* was observed between 1800 h and 1900 h feeding on the chrysalises of *Agraulis vanillae* (Gulf

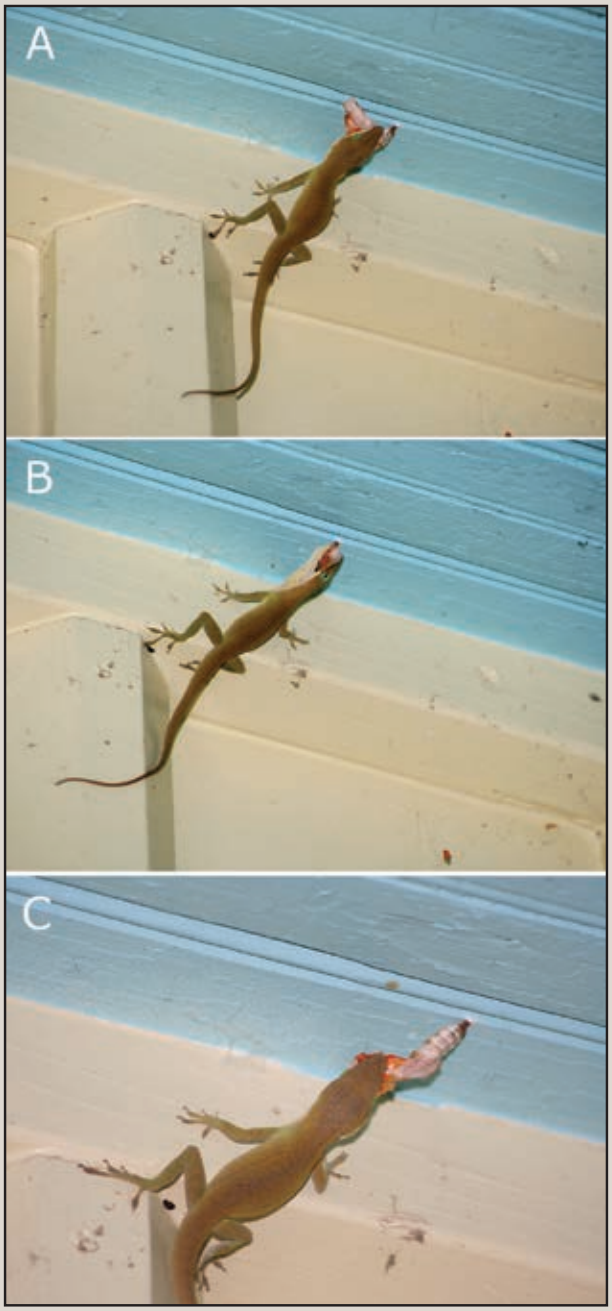

FIG. 1. A) *Anolis carolinensis* feeding on *Agraulis vanilla* chrysalis. B) Feeding on *Agraulis vanilla* chrysalis showing twisting motion. C) Feeding on *Agraulis vanilla* chrysalis showing yellowish liquid.

Fritillary). The chrysalises were located on the back porch of a house (32.514262°N, 85.611764°W; WGS84) and were made by caterpillars that had dispersed from a nearby native Passion Fruit vine (*Passiflora incarnata*) to pupate. During this time the lizard attacked and partially consumed two separate chrysalises. One chrysalis was 174.6 cm above the porch deck (or 254.6 cm above the ground surface) and the other was 327.0 cm (or 407.0 cm off the ground surface). The anole approached each chrysalis and nudged it several times with its nose, perhaps to elicit movement from the chrysalis that would indicate a butterfly had not yet emerged. It then latched onto the unattached end of the chrysalis and alternated between vigorous shaking of its head, twisting, bracing with all four feet and pulling backward, and quick chewing motions (Figs. 1A–B). Neither of the chrysalises detached from their substrate but the lizard did manage to break through the shell and tear off significant pieces, which the lizard then swallowed.

Anolis carolinensis is known to be insectivorous, and is assumed to consume a variety of arthropod species (Smith and Frost 1995. Handbook of Lizards: Lizards of the United States and of Canada. Cornell University Press, Ithaca, New York. 557 pp.). A captive anole was observed to eat butterflies but the species was not mentioned (Palmer and Braswell 1995. Reptiles of North Carolina. University of North Carolina Press. 448 pp.). The Gulf Fritillary is also known to secrete defensive compounds as an adult (Ross et al. 2001. J. Chem. Ecol. 27[6]:1219–1228), primarily 6-methyl-5-hepten-2-one. Ross et al. (*op. cit.*) observed deterred feeding by Green Anoles on the cockroach *Neostylopyga rhombifolia*, which also secretes this compound. Yellow and orange fluid was seen coming from the chrysalis once injured (Fig. 1C) but there did not seem to be any deterrent effect on the feeding behavior of the anole.

This observation is the first diet record of *Agraulis vanillae* being consumed by *A. carolinensis* and also the first documentation of an anole consuming a chrysalis.

***ASPIDOSCELIS EXSANGUIS* (Chihuahuan Spotted Whiptail). LIFE HISTORY IN MEXICO.** *Aspidoscelis exsanguis* is a widely distributed triploid hybrid-derived parthenogenetic lizard species (Good and Wright 1984. Experientia 40:1012–1014; Reeder et al. 2001. Amer. Mus. Novitat. 3365:1–61) in parts of Arizona, New Mexico, and Texas in the United States and in Sonora and Chihuahua in northern México. Aside from publication of distribution records, the taxonomy and biology of this species have not been studied in México. During extended field expeditions in preparation for publication of the tome on the herpetology of Chihuahua (see Lemos-Espinal and Smith 2007. Anfibios y Reptiles del Estado de Chihuahua, México/Amphibians and Reptiles of the State of Chihuahua, México. UNAM-CONABIO. México, D.F. 613 pp.), JAL-E collected lizards from a site in the northwestern quadrant of the state in late July 2002. We used them to clarify aspects of the life history of *A. exsanguis* in México where it is an entity with a name, but is an enigmatic species that is easily confused with congeners such as triploid parthenogenetic *A. sonorae* and *A. uniparens*, and gonochoristic *A. inornata* and *A. gularis scalaris* at certain stages of color pattern development. This study using ontogeny of color pattern clarifies identification of the species in Chihuahua, but more importantly it provides a basis for interpretation of the life history and age-related color pattern variation in *A. exsanguis*. These were not objectives of studies on the species conducted in the southwestern United States by Taylor and Caraveo (2003. Southwest Nat. 48:685–692) on clutch size and Bateman et al. (2010. J. Herpetol. 44:301–306) on growth rates and survivorship.

The study site (ca. 30.369833°N, 108.23575°W, WGS84; 1682 m elev.) in Chihuahua comprised an area of about five kilometers in length along the Río Piedras Verdes. This is a relatively flat area of ~20 m in width, on both sides of the southeasterly-directed river, which transitions from the bisected canyon floor to rocky hills and mountains. In the relatively flat portion of the site there was an abundance of Álamos trees (*Populus* sp.), with some interspaced oaks (*Quercus* sp.), with the latter being more abundant on the rocky hills and mountains. The dominant shrubs in the flat areas with ample open spaces and a variety of substrate types were manzanita (*Arctostaphylos* sp.), and scattered low-growing junipers (*Juniperus* sp.) which increased in abundance in the higher elevations. Where the river flows through the study site it is known as Red Rock Canyon, and alternatively as Cañón de la Tinaja, because of the large amount of clay in the soil and the reddish color of the rocks. Among the reptiles observed/collected at the site were *Sceloporus jarrovii* (Yarrow's Spiny Lizard), *S. virgatus* (Striped Plateau Lizard), *S. poinsetti* (Crevice Spiny Lizard), *Crotalus willardi silus* (Chihuahua Ridge-nosed Rattlesnake), *C. molossus* (Black-tailed Rattlesnake), *Thamnophis cyrtopsis* (Black-necked Gartersnake), and *Salvadora deserticola* (Big Bend Patch-nosed Snake). *Aspidoscelis exsanguis* was the only whiptail lizard species in this complex community of lizards and snakes, some of the latter being potential predators of Chihuahuan Spotted Whiptail, and it was easily the most ubiquitous and abundant of the species listed. This study site in Chihuahua also provides a noteworthy example of the presence of a parthenogenetic species of *Aspidoscelis* in a geographic area and local landscape devoid of any gonochoristic species of the genus (see Wright and Lowe 1968. Copeia 1968:128–138), a circumstance that was possibly correlated with the local abundance *A. exsanguis*.

Not only was *A. exsanguis* the most commonly encountered of the denizens of the flats in Red Rock Canyon, in numbers that prompted us to use the terminology "super abundance" (i.e., encountered in large numbers without special effort), it was also the least wary, most readily observable during its activities, and the most easily collected species. Consequently, 88 specimens of *A. exsanguis* were collected in late July which were catalogued into the collection of the Laboratorio de Ecología de la Unidad de Biotecnología y Prototipos (LEUBIPRO) in México City using the numbers 9782–9827, 9841–9844, 9849–9886. At the University of Arkansas, JMW measured the SVL of each specimen to the nearest 0.1 mm, and recorded the tail as being either complete or regenerated. The number of the caudal scale whorl immediately proximal to beginning of the regenerated portion was recorded counting distally from the first complete whorl at the base of the tail. Details of color pattern were recorded for each specimen to facilitate the first analyses of ontogenetic changes with growth in SVL in the species. Also noted was the reproductive condition of each specimen, there being only two categories resulting from the late July date of collection, either immature (~31–60 mm SVL) or of adult size and reproductively quiescent for the year (~61–85 mm SVL), the latter range based on clutch data for the species observed in New Mexico by Taylor and Caraveo (*op. cit.*). Statistical analyses were performed at the University of Arkansas on a

PC using institutionally licensed JMP software (Version 11 SAS Institute, Inc., Cary, North Carolina, Copyright © 2013).

As specimens were being collected it seemed that the late July 2002 composition of the array of *A. exsanguis* in Red Rock Canyon continuously ranged in SVL from recent hatchlings (young-of-year; YOY) to large adults of several years in age. However, as they were being measured, a gap in SVL coverage spanning ~3452 mm SVL was noted. Further analyses revealed that each of the lizards was part of one of four SVL groups characterized by consistently different sets of characters of the dorsal color pattern, which had developed from one through either three or four reproductive activity cycles. The dorsal pattern of YOY in the sample of *A. exsanguis* included three pairs of contrasting longitudinal yellow-hued stripes (ventral to dorsal on each side the straight-margined laterals and dorsolaterals and the unevenly margined paravertebrals) and blackish intervening fields with barely visible spots (stage one), which transitioned to less contrast between stripes and fields and more distinct spots (stage two), which transitioned to brown-black fields, yellow-tan stripes, a profusion of tan spots, and a reticulated pattern of pale markings on the hind limbs (stage three), which transitioned to low contrast stripes and fields, profusion of spot on the stripes and in the fields, and spotted hind limbs (stage four). Analysis of SVL data spanning each of the four stages of ontogenetic pattern development revealed that the mean for each one was significantly different from all others ($P = 0.05$). Stage one included only two recent YOY of 31.3 and 32.4 mm SVL (mean 31.8 ± 0.55), though more of them were observed in Red Rock Canyon, but not collected. Stage two included three immature and 27 mature lizards (with similar dorsal patterns) of 53.070.5 mm SVL (mean 64.6 ± 0.85). Stage three included 29 adults of 66.9–81 mm SVL, mean 73.0 ± 0.69. Stage four included 27 adults of 73.7–84.6, mean 79.8 ± 0.57. We found a strong correlation between SVL and stage of dorsal pattern ontogeny (adjusted $r^2 = 0.6954$, $P \leq 0.0001$). The size range in which the transition from group one to two occurred could not be determined because of absence of specimens between 34 and 52 mm SVL, transition of stage two to stage three occurred from 67 to 71 mm SVL, and transition from stage three to stage four occurred from 77 to 78 mm SVL. We hypothesize that these data support the hypothesis that the sample of *A. exsanguis* from Chihuahua comprised four year-classes represented by the stages of ontogenetic dorsal pattern development.

In summary, we propose that the life cycle of *A. exsanguis* at the GPS coordinates noted for Red Rock Canyon proceeds as follows. Hatchlings appear from mid-July into August and grow rapidly until they become inactive for the year in October. Immature lizards with a range of SVL lengths emerge from inactivity for their second growing season in the following April to May; the largest (i.e., earliest) of the previous year hatchlings possibly attain reproductive status (~61 mm SVL; see Taylor and Caraveo, *op. cit.*) in the second summer, whereas the smallest (i.e., latest) hatchlings of the previous year would not attain reproductive maturity until the third summer. Most lizards transition to the fourth and final distinctive stage of pattern ontogeny, and maximum reproductive potential, in the fourth and last summer of life. The largest among the specimens of *A. exsanguis* from Red Rock Canyon was only 84.6 mm SVL, whereas Taylor and Caraveo (*op. cit.*) reported a lizard of 93 mm SVL from New Mexico. Although we note the presence of several potential predators of Chihuahuan Spotted Whiptail in Red Rock Canyon we hypothesize that death by senescence following last clutch production is the usual basis for the end of the life cycle. Only 12 of 88 (13.6%) specimens exhibited regenerated tails, which included ontogenetic stages two (individuals of 54.0, 62.8 mm SVL), stage three (66.9, 69.5, 73.2, 73.5, 76.2, 78.2 mm SVL), and stage four (73.7, 78.2. 82.5, 84.2 mm SVL), distal to caudal whorls 1444, mean 23.8 ± 2.51. These data possibly indicate that predation encounters and escapes by tail autotomy are infrequent occurrences in *A. exsanguis* in Red Rock Canyon, Chihuahua.

Specimens referenced herein were collected in Chihuahua by JAL-E and imported to the United States for study under authority of permits provided by the government of México.

JAMES M. WALKER, Department of Biological Sciences, University of Arkansas, Fayetteville, Arkansas 72701, USA (e-mail: jmwalker@uark.edu); **JULIO A. LEMOS-ESPINAL**, Laboratorio de Ecología-UBIPRO, FES Iztacala UNAM, Av. Los Barrios No. 1, Los Reyes Iztacala, Tlalnepantla, México – 54090 (e-mail: lemos@unam.mx).

***ASPIDOSCELIS GULARIS SEPTEMVITTATA* (Mexican Plateau Striped Whiptail). REPRODUCTION.** *Aspidoscelis gularis septemvittata* (Walker 1981a. Copeia 1981:826–849; Walker 1981b. Copeia 1981:850–868) is a moderately large and persistently striped lizard that inhabits parts of the mountainous border region of Trans-Pecos Texas, United States, and similar areas in adjacent Chihuahua State, México. We assessed size and reproductive characteristics for this biologically poorly known species based on 30 specimens from geographically proximate sites in Chihuahua identified by Walker et al. (2001. Copeia 2001:747–765). No other congeners were observed at these sites, which may in part account for the observed abundance of *A. g. septemvittata* by JAL-E. Data for SVL and clutch size based on measurements and dissections of lizards in the sample designated as SEPT-CMX1 (Walker et al., *op. cit.*) are presented herein by ranges of variation, sex, and/or means (to one decimal place) ± 1 SE. Statistical analyses were performed at the University of Arkansas on a PC using institutionally licensed JMP software (Version 11 SAS Institute, Inc., Cary, North Carolina, Copyright © 2013)

The sample collected 6–10 July 1999 by JAL-E, during preparation of the herpetofaunal study by Lemos-Espinal and Smith (2007. Anfibios y Reptiles del Estado de Chihuahua, México / Amphibians and Reptiles of the State of Chihuahua, México. UNAM-CONABIO. México, D.F. 613 pp.), included 14 males and 16 females. All males were sexually mature based on swollen testes and enlarged femoral pores, and they represented more than one year-class based on the wide SVL range of 40 mm (71, 73, 77, 78, 79, 82, 85 [2], 87 [2], 89, 95, 105, 111, mean 86.0 ± 3.04). Based on the content of all five samples of *A. g. septemvittata* collected from Chihuahua by JAL-E and reported by Walker et al. (*op. cit.*), only 14% exceeded 100 mm SVL. Sample SEPT-CMX1 also included one juvenile female (58 mm SVL) and 15 adult females based on the smallest gravid individual [64, 68, 69, 70, 71, 73, 74, 76, 79, 81, 83 (2), 85, 86, 94 mm SVL, mean 77.1 ± 2.12]. They also represented more than one year-class based on the wide SVL range of 30 mm. Based on the content of all five samples of *A. g. septemvittata* collected from Chihuahua by JAL-E and reported by Walker et al. (*op. cit.*), only 10% exceeded 90 mm SVL. The size data indicate that males of *A. g. septemvittata* in Chihuahua can attain a larger mean SVL than females ($P = 0.05$). In the SEPT-CMX1 sample, clutches of two were present in three females (64–70 mm SVL), clutches of three were present in three (71–74 mm SVL), clutches of four were present in five (79–85 mm SVL), and a clutch of six was present in one (94 mm SVL), mean clutch size 3.4 ± 0.84. Linear regression calculated in JMP indicates a nearly

perfect correlation between SVL and clutch size for the 12 gravid Chihuahua females of *A. g. septemvittata* (based on adjusted r^2 = 0.92; $P \leq 0.0001$). We offer the hypothesis that simultaneous July clutch production among the year classes of *A. g. septemvittata* represented in sample SEPT-CMX1 (i.e., 64–94 mm SVL) from Chihuahua allows for the possibility that one late clutch is likely produced in the first activity cycle of maturity and a minimum of an early and a late clutch develop in the second and subsequent years of maturity.

Specimens referenced herein were collected in Chihuahua by JAL-E and imported to the United States for study under authority of permits provided by the government of México. The specimens were deposited in the collections of the University of Colorado Museum of Natural History, Boulder, Colorado, and Laboratorio de Ecología, Unidad de Biotecnología y Prototipos, Facultad de Estudios Superiores Iztacala, UNAM, Estado de México, México. They were represented by JAL-E numbers at the time of the laboratory examinations, and referenced as sample SEPT-CMX1 in a systematic study that included the authors (Walker et al., *op. cit.*) comprising the following: Chihuahua: Polvorillas (= Piedras Encimadas), 28.793389°N, 104.225222°W, 1440 m elev. (6 July 1999 [JAL-E 3606–3612, N = 7], 7 July 1999 [JAL-E 3619–3630, 3654–3656, N = 15]; 9 July 1999 [JAL-E 3744, N = 1]); Llano El Nito, a flat area 1.5 km NW of Polvorillas, 1450 m elev. (8 July 1999 [JAL-E 3699, N = 1]; 9 July 1999 [JAL-E 3708–3711, N = 4]); Rancho Virulento base of Sierra El Virulento, 28.761361°N, 104.335694°W, 1502 m elev. (10 July 1999 [JAL-E 3749–3750, N = 2]).

***ASPIDOSCELIS INORNATA* (Little Striped Whiptail). NORTHERN LIFE HISTORY.** The geographic distribution of *Aspidoscelis inornata* (Little Striped Whiptail) spans more than 1500 km between the northwestern corner of New Mexico (USA) and southern Zacatecas and San Luis Potosi states, México (see map in Wright and Lowe 1993. J. Arizona-Nevada Acad. Sci. 27:129–157). We assessed size and reproductive characteristics of *A. inornata* from San Juan Co., New Mexico, which marks the northern distributional limits of the species. We undertook the analyses because studies of latitudinally extensively distributed *A. tigris* (e.g., McCoy and Hoddenbach 1966. Science 154:1671–1672; Pianka 1970. Ecology 51:703–720; Burkholder and Walker 1973. Herpetologica 29:7683) have demonstrated the desirability of assessing life history characteristics of whiptail lizard species at different latitudes and altitudes to understand regional adaptations. We did not use the trinomial *A. i. junipera* (sensu Wright and Lowe, *op. cit.*) for the populations of diminutive lizards (maximum observed SVL = 70 mm and body mass 7.8 g) in this area so as to avoid the potential controversy introduced by the revised subspecies allocation based on mtDNA by Sullivan et al. (2014. Copeia 2014:519–529). Our study area was near the ecologically complex Bisti/De-Na-Zin Badlands, administered by the US Bureau of Land Management, in San Juan Co. in the four corners area of the western United States. No other species of whiptail lizards known from San Juan Co. (e.g., triploid parthenogenetic *A. velox* and gonochoristic *A. tigris*) were observed at the sites investigated which may in part account for the exceptional abundance of *A. inornata* in and near the vast Bisti/De-Na-Zin Badlands. Data for SVL, sex, and clutch size based on measurement and dissection of the lizards in the University of Arkansas Department of Zoology (UADZ) sample are presented with ranges of variation, sex as a ratio, and/or means (to one decimal place) ±1 SE.

Numbers of males and females of *A. inornata* (M:F), by size (as 5-mm SVL increments if applicable) were used to track sex ratio by size among the 25 specimens collected in May–June 2013 and 11 collected in early July 2013 (Table 1). According to our observation in San Juan Co., and the study of *A. inornata* by Christensen (1971. Amer. Mus. Novitat. 2442:1–48) in Bernalillo Co., central New Mexico, young-of-year hatch in the last part of July, remain active until early September, and become inactive until April–May at ~38–44 mm SVL. Thus, for lizards collected in May–June 2013 in San Juan Co. (Table 1) we infer that juvenile individuals of 42–48 mm (mean 45.8 ± 1.20, N = 5) were hatched in the summer of 2012. Adult females of 59–68 mm (mean 62.8 ± 1.03, N = 8) and adult males of 57–70 mm (mean 62.1 ± 0.91, N = 12) in the sample are not significantly different in size, and were conservatively estimated to have hatched in the summer of 2011. Numbers of males and females collected near the Bisti/De-Na-Zin Badlands in early July 2013 (Table 1) included five juveniles of 48–53 mm (mean 50.2 ± 0.80) and also six adults of 57–66 mm (mean 61.8 ± 1.25). We concluded that individuals of *A. inornata* at the latitude of the Bisti/De-Na-Zin Badlands do not attain reproductive maturity in the summer following that of hatching. Christensen (*op. cit.*) also concluded that few if any individuals of the species attain sexual maturity in the year following hatching in the Albuquerque area in Bernalillo Co. We could not accurately determine whether either our May–June or July 2013 samples included individuals in the fourth summer of life based on SVL data.

In the May–June sample seven of eight adult females had yolked ovarian follicles; none of the July adult females were gravid. Clutch size was 2.9 ± 0.14 (range 2–3) eggs. The relationship between clutch size and SVL was not significantly correlated for the seven San Juan Co. females of *A. inornata* (based on adjusted r^2 = 0.20; P = 0.1747). We compared it with data for *A. pai* (= *A. i. pai*; Pai Striped Whiptail) from northcentral Arizona. It had a mean SVL of 65.3 ± 1.08 mm, 61–72 mm (N = 11), of which only two females exceeded 70 mm (Walker et al. 2012. Herpetol. Conserv. Biol. 7:265–275). Clutch size was 3.18 ± 0.18 (range 2–4) for *A. pai* and it was not significantly correlated with SVL (adjusted r^2 = 0.27, P = 0.436). Although the maximum clutch size for *A. pai* exceeded that of *A. inornata*, mean clutch sizes for the two were similar.

For this study we examined 36 preserved specimens of *A. inornata* from the UADZ collection obtained by JEC in 2013 as follows:

TABLE 1. Numbers of males and females of *Aspidoscelis inornata* from San Juan County, New Mexico, recorded as 5-mm SVL increments where possible within the total range to track sex ratio by size among specimens collected in May–June and July 2013.

Period	Total SVL Range in 5-mm Increments and Sex Ratio (M:F)							
May–June 2013	42–70 14:11	42–44 2:0	45–49 0:3	50–54 0:0	55–59 2:1	60–64 9:5	65–69 0:2	70 1:0
July 2013	48–66 4:7	—	48–49 0:1	50–54 2:2	55–59 0:1	60–64 2:2	65–66 0:1	—

New Mexico, San Juan Co., jct NM Hwy 371 & CR 7290, 11.2 km N of Bisti/De-Na-Zin access on 371 (36.325639°N, 108.2560755°W, ~1847 m elev.) in an active Prairie Dog town on the E side of Hwy 371, ~47 km S of San Juan River crossing in Farmington on Hwy 371: UADZ 9201–9210 (N = 10), 26 May 2013; UADZ 9213–9222 (N = 10), 27 May 2013; UADZ 9255–9256 (N = 2), 5 June 2013; UADZ 9257–9259 (N = 3), 6 June 2013; UADZ 9334–9338 (N = 5), 8 July 2013; UADZ 9368–9373 (N = 6), 17 July 2013.

We thank the New Mexico Department of Game and Fish for permit 1850 granted to JEC to collect lizards in the state in 2012 and 2013.

***ASPIDOSCELIS SEXLINEATA VIRIDIS* (Prairie Racerunner). EXTREME COLOR VARIANT.** We have collectively examined >10,000 specimens and numerous photographs of *Aspidoscelis sexlineata* from its vast geographic range in the United States (Trauth 1980. Ph.D. Dissert., Auburn Univ., Auburn, 201 pp.; Trauth 1992. Texas J. Sci. 44:437–443; Trauth and McAllister 1996. Cat. Amer. Amphib. Rept. 628:1–12) and Mexico (Pérez-Ramos 2010. Southwest. Nat. 55:419–225). Although ontogenetic changes and sexual dimorphism occur in each of the three recognized subspecies of *A. sexlineata* (see de Quieroz and Reeder 2012. SSAR Herpetol. Circular 39:32–51), these variations have been within the scope of the respective diagnoses provided for each taxon (Lowe 1966. J. Arizona Acad. Sci. 4:44–45; Trauth 1980, *op. cit.*; Trauth 1992, *op. cit.*; Trauth and McAllister 1996, *op. cit.*; Pérez-Ramos 2010, *op. cit.*). An adult female of *A. sexlineata viridis* from western Nebraska, captured alive on 25 May 2014 and shipped to SET on 28 May 2014 by JBI, ARH, and LCC, exhibited such extreme aspects of dorsal and ventral coloration as to necessitate commemoration of it in the literature. It was the only such individual among the thousands of *A. s. viridis* observed by JBI at the Nebraska site during 35 years of study. The lizard was caught in a bucket trap in a drift fence array of ~1.2 km in length near Road 181 (41.9345°N, 102.4825°W, NAD83; ~1173 m elev.), north of Gimlet Lake, Garden Co., Nebraska, USA. The habitat there consisted of upland naturally open-structured sandhills, but with an active invasion of the widely distributed Asian adventive, Cheatgrass (*Bromus tectorum*). The unique specimen has been catalogued by SET as Arkansas State University Museum of Zoology (ASUMZ) 33235, along with three normally patterned *A. s. viridis* (ASUMZ 33230–33232) also subsequently caught in the same bucket trap. Examined for comparisons were two typical specimens of *A. s. viridis* (ASUMZ 33233–33234), collected in a gravelly ravine (41.6757°N, 102.3852°W, NAD83; 1235 m elev.), ~10.5 km SE of the previously noted site, Garden Co., Nebraska, USA.

The dorsal color pattern in ASUMZ 33235 (SVL = 62 mm; complete tail length = 138 mm) in life was unique because of the absence of the green suffusion on the head and body, which is typically present in adult females of *A. s. viridis*. The striping pattern (ventral to dorsal) consisted of a pair of barely visible and essentially vestigial ventrolaterals, three pairs of primary stripes so termed because they are fixed in position among individuals of this taxon, and a secondary vertebral stripe so termed because of variation among individual lizards (Table 1). The ground color between the stripes, termed fields, consisted of hues of dark brown (Fig. 1-middle; Table 1) rather than the hues of green suffusions on tan or light brown characteristic of normal adult females (Fig. 1-upper) and males (Fig. 1-lower) of *A. s. viridis* from Nebraska. The dorsal tail coloration was dark brown between the dorsolateral and paravertebral stripe extensions in the unusual specimen, but tan in typical specimens.

Stunningly, adult female ASUMZ 33235 had a dusky black chin and throat that has not been observed in the normal color pattern of any other species in the *Aspidoscelis sexlineata* species group in the United States. However, dusky to black throat colorations characterize some populations of *A. costata* in the *A. sexlineata* group in western Mexico (Duellman and Zweifel 1962. Bull. Amer. Mus. Nat. Hist. 123:155210) and of *A. tigris*

FIG. 1. Dorsal color patterns of live specimens of a normal male (ASUMZ 33233, lower) and female (ASUMZ 33234, upper) *Aspidoscelis sexlineata viridis* in contrast to the variant female (ASUMZ 33235, middle).

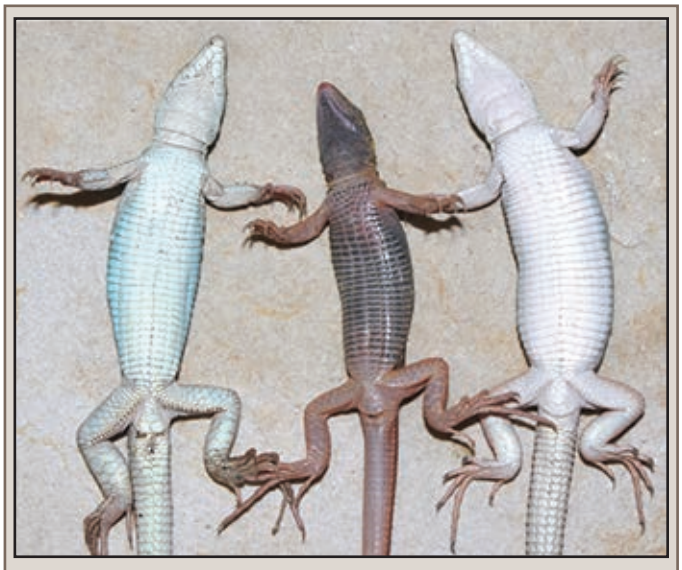

FIG. 2. Ventral color patterns of live specimens shown in Fig. 1 (ASUMZ 33233, at left).

TABLE 1. Dorsal color pattern components in the variant of *Aspidoscelis sexlineata viridis* (ASUMZ 33235) from Garden County, Nebraska, USA.

Pattern Component	Location of Component	Color(s)	Extent of Presence
Paired Ventrolateral Stripes (Vestigial)	Dorsal to Ventral Scales	GrayWhite	Head and Body (Indistinct)
Paired Lateral Stripes (Primary)	Dorsal to Ventrolaterals	GrayWhite to GrayTan	Head and Body
Paired Dorsolateral Stripes (Primary)	Dorsal to Laterals	GrayWhite to GrayTan	Head, Body, and Tail
Paired Paravertebral Stripes (Primary)	Dorsal to Dorsolaterals	GrayWhite to GrayTan	Head, Body, and Tail
Single Vertebral Stripe (Secondary)	Along Midsagittal Plane	Tan to Pale Brown	Head and Body
Fields (= Ground Color)	Between Stripes	Predominantly Dark Brown	Body

(Tiger Whiptail) in the *A. tigris* group in the southwestern USA (Dessauer et al. 2000. Bull. Amer. Mus. Nat. Hist. 246:1148). The dusky black pigmentation was also present in the scalation of the thoracic and abdominal surfaces of ASUMZ 33235 (Fig. 2-middle). Equally unexpected was the ventral distribution of pink-red pigmentation on the entire venter, even involving parts of the scales with dusky black pigmentation, a coloration that has not been reported in *A. sexlineata*. Entirely pink-red pigmentation also characterized the ventral aspects of the legs and tail of the female. The typical adult females from the study area had immaculate white venters (Fig. 2-right), whereas males had predominantly white venters with faint hues of blue in the thoracic and abdominal regions and under the legs (Fig. 2-left).

In ASUMZ 33235 the mesoptychial scales bordering the gular fold were abruptly enlarged and the postantebrachial scales on the posterior aspects of the forearms were only slightly enlarged from granular size in both the typical and atypical females depicted in Fig. 2. Moreover, data for the granules = scales around midbody, 72; granules from occipital scales to first row of caudal scales, 182; granules between the paravertebral stripes, 11; and femoral pores, 15 left/16 right were within known ranges of variation (Trauth 1980, *op. cit.*; J. M. Walker, unpubl.).

Examples of extreme color pattern variants among gonochoristic species in both the *A. sexlineata* and *A. tigris* species groups have been reported. With reference to the *A. sexlineata* group, Christiansen and Degenhardt (1969. Texas J. Sci. 21:95–97) reported a variant of *A. gularis* (Texas Spotted Whiptail) from New Mexico with an unusual dorsal pattern in which all traces of the pale stripes had been replaced by spots, and Walker et al. (1996. J. Herpetol. 30:271–275) reported an individual of *A. inornata* (Little Striped Whiptail) that lacked all traces of stripes collected from a population of normally striped lizards in Chihuahua, Mexico. For the *A. tigris* group, both Acre et al. (2012. Southwest. Nat. 57:206–207) and Ballinger and McKinney (1968. Herpetologica 24:264–266) reported individuals of *A. marmorata* (Marbled Whiptail) from Texas and New Mexico, respectively, that were termed patternless morphs because they lacked a contrasting dorsal pattern. Based on data for color pattern variation in *A. gularis* (Walker 1981a. Copeia 1981:826–849; Walker 1981b. Copeia 1981:850–868), *A. inornata* (Wright and Lowe 1993. J. Arizona–Nevada Acad. Sci. 27:129–157; Walker et al. 2009. Herpetol. Rev. 40:276–282; Sullivan et al. 2013. Copeia 2013:366–377), and *A. tigris* (Hendricks and Dixon 1986. Texas J. Sci. 38:327–402), it is evident that the extreme variant of *A. s. viridis* reported herein is in a class apart from the other examples cited because it represents a categorical departure from all previously reported variation in the species (Figs. 1–2). Although the causation of the extreme color pattern variation in ASUMZ 33235 cannot be ascertained, there are only two possible explanations for its existence. Either it was the product of a rare non-genetic developmental anomaly, from which normally patterned offspring would be expected, or it is the result of one or more mutations, from which the aberrant pattern could have possibly been perpetuated in future generations had reproduction occurred.

Field work by JBI, ARH, and LCC leading to the reported discovery was supported by Earlham College Summer Research Funds. Collections of individuals of *A. s. viridis* were made possible under the authority of permit #312 (2013–2014) from the Nebraska Game and Parks Commission issued to JBI.

IVERSON,** Department of Biology, Earlham College, Richmond, Indiana 47374, USA (e-mail: johni@earlham.edu); **JAMES M. WALKER**, Department of Biological Sciences, University of Arkansas, Fayetteville, Arkansas 72701, USA (e-mail: jmwalker@uark.edu).

***CROCODILURUS AMAZONICUS* (Crocodile Tegu). DIET**. *Crocodilurus amazonicus* is a medium-sized neotropical lizard widely distributed throughout the Amazon Basin and Orinoco River. It prefers semi-aquatic habitats, often being found near water. There are few published accounts of the ecology and natural history of this lizard. Vanzolini and Valencia (1965. Arq. Zool. São Paulo 13:7–46) described *C. amazonicus* dentition as insectivorous, whereas Presch (1974. Herpetologica 30[4]:344–349) suggested that *C. amazonicus* dentition is adapted for grasping and tearing large prey. Vertebrates have been recorded for the diet of *C. amazonicus*, including anurans, a snake, and fish (Costa et al. 2005. Herpetol. Rev. 36:174–175; Mesquita et al. 2006. J. Herpetol. 40:221–229). The identity of fish species consumed and the method of prey capture remain unknown.

On 25 March 2014 we observed *C. amazonicus* preying on a fish, *Pterophyllum scalare* (Discus Flag) (Fig. 1A, B), on the Rio Solimões in municipality of Iranduba, Amazonas, Brazil

FIG. 1. *Crocodilurus amazonicus* consuming its prey, *Pterophyllum scalare.*

(3.227210°S, 60.004606°W; WGS84). The lizard was seen diurnally active on a lilypad (*Victoria amazonica*) capturing the fish, considerably larger than the lizard's head. On the lilypad and walking on its edges, the lizard quickly stuck its head in the water, grabbing the fish with its teeth. The presence of lilypads might facilitate visualization of prey in the water and prevent the prey from seeing the shadow and reflection of the hunting lizard.

***CTENOTUS GRANDIS GRANDIS* (Grand Ctenotus). BIFURCATION.** A common anti-predation strategy in many lizard species is the ability to drop all or part of their tail, caudal autotomy, when attempted predation occurs (Arnold 1984. J. Nat. Hist. 18:127–169; Bateman and Fleming 2009. J. Zool. 277:1–14). Loss of the tail, or part of, allows for the lizard to remove itself from the constraints of the predator and retreat, leaving the predator distracted by or to feed on the tail (Arnold 1984, *op. cit.*; Bateman and Fleming 2009, *op. cit.*; Sownes and Shine 2001. Ecology 82:1293–1303). Following the loss of all or part of a tail, it is often regenerated; however, if the autotomy process is not completed and the tail only partially detaches, the regeneration process may still be triggered if sufficient damage has occurred. In the event of a partial autotomy, if enough muscle and/or bone remain intact, the partially autotomized tail portion may remain and a second regeneration tail may begin to grow in addition to the existing tail, resulting in two tails or bifurcation (Bateman and Fleming 2009, *op. cit.*; Dudek and Ekner-Grzyb 2014. Natura Sloveniae 16[1]:65–66). Tail bifurcation has been recorded in a number of reptiles, particularly lizard species that frequently regenerate tails after loss.

Ctenotus grandis grandis is a large (up to 105 mm SVL) intricately patterned scincid that inhabits arid zone habitats, often dominated by spinifex (*Triodia* spp.) on sandy loam substrates in the western interior of Western Australia to central Northern Territory.

On 6 April 2011, an adult *Ctenotus grandis grandis* with a bifid tail was caught in a pitfall trap as we undertook a faunal survey near Davidson Creek, Western Australia (23.302942°S, 120.234872°E; WGS84). The tail bifurcation occurred along the posterior length, originating approximately mid-way along the tail resulting in two morphologically similar bifid tails. The bifurcation resulted in the growth of a dorsal and ventral length of tail. The length of the ventral (48 mm) bifid tail was slightly longer than the dorsal (32 mm). The upper bifid length was morphologically consistent with the remainder of the anterior length of tail while the lower bifid length was mirrored the ventral surface of the upper bifid tail its entire length. A small kink was present in the dorsal tail length indicating it is likely to be the original tail which possibly suffered multiple injuries resulting in the original tail damage that lead to the bifurcation.

The bifurcation did not appear to interfere with any movement or use of the tail by the animal. No caudal use of behavior such as luring or displays by the animal were observed and no other individuals of this subspecies or other *Ctenotus* species were observed performing any caudal displays at the site. However, the extent of caudal use by *C. g. grandis* and congeners is not well known. This is the first record of tail bifurcation in the *Ctenotus grandis* complex. As bifurcation is recognized as the result of previous injury and not caused by deformity of any form (Lynn 1950. Herpetologica 6:81–84; Bateman and Fleming 2009, *op. cit.*), there is no indication that bifurcation affects the natural behavior of specimens with this abnormality.

RYAN J. ELLIS, Department of Terrestrial Zoology, Western Australian Museum, 49 Kew Street, Welshpool, Western Australia, 6106, Australia; e-mail: Ryan.Ellis@museum.wa.gov.au.

***EULAMPRUS QUOYII* (Eastern Water Skink). CANNIBALISM.** *Eulamprus quoyii* is a medium-sized terrestrial diurnal viviparous lygosomine skink widespread in riparian and mesic habitats of the coastal plain, hinterland, and ranges of most of eastern mainland Australia (Cogger 2014. Reptiles and Amphibians of Australia [7th ed.]. CSIRO Publishing, Collingwood, Victoria, Australia. xxx + 1033 pp.). This note documents a case of cannibalism by a large adult *E. quoyii* of a juvenile conspecific and discusses the possible significance of this behavior; parturition of neonates in a clutch at separated sites is also reported.

On 3 January 2014, ~1430 h, on a sunny day, T_A ~31°C, in a suburban backyard in Cooranbong, Lake Macquarie, New South Wales, Australia (33.08°S, 151.45°E, WGS84; 12 m elev.), where *E. quoyii* of all ages and size classes are common, TJA observed a large adult (SVL ~110 mm, total length ~310 mm) *E. quoyii* chasing a recent neonate (SVL ~40 mm, total length ~110 mm) conspecific moving in coarse bark chips in a flower bed, dashing about in a zig-zag fashion. The adult seized the neonate over the midbody and raced off about 3 m to a less exposed area; the adult then bit down hard on the neonate several times, and after ~3 minutes the neonate was limp and apparently dead. This mastication induced caudal autotomy at a point ~50 mm from the tail base, whereupon the adult dropped the body (which did not move), then seized and swallowed the writhing tail indicating a strong attraction towards moving prey. After seizure and swallowing of the autotomized tail portion, the adult searched around, located and picked up the body of the neonate, which it began to manipulate in preparation for swallowing. However, another adult *E. quoyii*, apparently attracted by this activity, attempted to kleptoparasitize the prey item, whereupon the first adult *E. quoyii* ran off on concrete paving around the corner of the house (a distance of ~9 m and out of sight of the pursuing lizard) with the body of the neonate in its mouth, and had almost completed swallowing when it was lost to view. The duration of observation of these events was ca. 10 minutes.

Adult *E. quoyii* at this locality are opportunistic feeders that consume numerous invertebrate species including live and dead spiders and slugs (TJA, pers. obs.); they have also been observed to catch and consume adults of the small lygosomines *Lampropholis delicata* and *Saproscincus mustelina* on several occasions, and have been seen in vigorous pursuit of conspecific neonates (TJA, pers. obs.). Given that neonate *E. quoyii* are only a little larger than adults of these other taxa, this might explain the willingness of adult *E. quoyii* to prey on conspecific neonates and small juveniles. Neonates can run very fast for their size and rapidly learn to hide themselves in narrow crevices when pursued. In over 10 years of observation at the locality, this was the only successful capture of a neonate recorded, although this likely occurs much more frequently. With ontogeny, a size refuge from cannibalism is evidently obtained (at SVL ~60 mm), at which size juvenile *E. quoyii* learn that it is safe to approach mature adults apparently without fear of assault, and also that they can approach adults much more closely from the rear than from head-on (TJA, pers. obs.). There is a reported case of whole-clutch filial

cannibalism by the skink *Eutropis longicaudata* (Huang 2007. Behav. Ecol. 19[6]: doi:10.1093/beheco/arn109), and cannibalism is well known in a number of lizard species including skinks (Pough et al. 1998. Herpetology. Prentice-Hall, London, UK. 577 pp.).

Given good conditions, *E. quoyii* can produce large litters of up to ~12; the neonates are born at intervals at different sites over a period of two, or occasionally three, days (TJA, pers. obs.). For example, in December 2002, around midday in very warm sunny weather at the same locality, TJA observed parturition in a large gravid *E. quoyii*, where the female arched her tail as if to defecate, however instead deposited a neonate on an open flat concrete area next to a fishpond, and then ran into undergrowth at a point ~10 m distant from the parturition site, presumably to deposit another neonate. Neonate *E. quoyii* at this latitude have been observed between early spring and late autumn, indicating that some adult females may produce multiple clutches in one season, although most neonates appear around mid-summer (TJA, pers. obs.); this reproductive mode provides the potential for very rapid increase in local population size. We suspect cannibalism in *E. quoyii* is widespread, and that this species regulates local population sizes through cannibalism of neonates and small juveniles, at least in anthropogenic urban habitats. Further study is required to determine the validity of our hypothesis. We further hypothesize that parturition of neonates in a clutch at separated sites may be a strategy to minimize cannibalism in *E. quoyii*. In the mild climate at this temperate locality, parturition may occur at all times of the year except winter when *E. quoyii* is mostly inactive (TJA, unpubl. data), hence predatory threat to neonates from large conspecifics also exists throughout most of the year.

TERENCE J. ANNABLE, Faculty of Science and Mathematics, Avondale College, PO Box 19, Cooranbong, New South Wales, Australia 2265; **DEAN C. METCALFE**, PO Box 4056, Werrington, New South Wales, Australia 2747 (e-mail: dean_metcalfe@yahoo.com.au).

***GEHYRA AUSTRALIS* (Tree Dtella) and *GEHRYA PILBARA* (Pilbara Dtella). ENVIRONMENTALLY CUED HATCHING.** Environmentally cued hatching (ECH), whereby hatching competent embryos can choose their own hatching date by assessing and responding to risks, can include early hatching, delayed hatching, or synchronous hatching (Warkentin and Caldwell 2009. *In* Dukas and Ratcliffe [eds.], Cognitive Ecology II. The Evolutionary Ecology of Learning, Memory and Information Use, pp. 177–200. University of Chicago Press, Chicago, Illinois). A recent review has extended ECH to reptiles (Doody 2011. Integr. Comp. Biol. 51:49–61). For instance, early hatching in Delicate Skinks (*Lampropholis delicata*) is likely an antipredator response to egg predation (Doody and Paull 2013. Copeia 2013:160–165). Although a few other lizard species can hatch early in response to being handled, ECH is not known to occur for most lizard species, presumably due to the difficulty in finding their eggs (Doody et al. 2009. Q. Rev. Biol. 84:229–252), and due to the erroneous assumption by researchers that eggs hatching while being handled reflects coincidence. Herein we report on observations of early hatching in response to handling in the Tree Dtella (*Gehyra australis*) and the Pilbara Dtella (*Gehyra pilbara*). We comment on implications for predator avoidance.

During the afternoon of 1 May 2013 at the El Questro Station in El Questro Wilderness Park, Western Australia (16.006398°S, 127.98420°E) some campers inadvertently dislodged bark from a *Eucalyptus* tree while tying off a shelter, exposing two gecko eggs that were laid under the bark. The campers placed the eggs in a small plastic container with a small amount of leaf litter and bark and brought them to us at 0924 h. At this stage one egg had pipped; the eggshell was fractured and pushed outwards at a single point. In anticipation of hatching both eggs were placed on a plate with some leaf litter and bark for photographs. As the first hatchling was being photographed the second egg pipped (0929 h) and its hatchling emerged (0934 h) and was photographed (Fig. 1). Hatching was steady and without any sudden movements for both eggs; in contrast, once the hatchlings emerged from the eggs they quickly dispersed to the nearest cover (leaf litter and bark at edge of plate). The second hatchling was in the process of sloughing its skin (Fig. 1), which is not uncommon in reptiles (Alibardi and Gill 2007. J. Anat. 211:92–103). The hatchlings were identified as *Gehyra australis* based on morphology, location of the nest site coloration, and their brittle-shelled eggs. Both hatchlings were released at site of egg collection the following morning.

PHOTO BY R. ELLIS

FIG. 1. Hatching *Gehyra australis* from the Kimberley region, Western Australia.

During the evening of 11 November 2008 we discovered two gecko eggs in a hole in a termite mound in tropical savannah, about 300 km SE of Karratha, Western Australia (22.459969°S, 118.993245°E). As the eggs were removed from the hole they hatched in hand, and the hatchlings immediately ran quickly in an attempt to escape. The hatchlings were identified as *Gehyra pilbara* based on morphology, coloration, brittle-shelled eggs, and the location of the eggs in a termite mound. The hatchlings were released into leaf litter adjacent to their original termite mound.

The handling-induced hatching in both species likely reflects early hatching in response to an increase in perceived predation risk. There is a misconception that the hatching of eggs during handling reflects a coincidence. In fact, it is highly likely that vibrations due to handling are perceived as stimuli emitted by a predator (Doody and Paull, *op. cit.*). Similar hatching in response to handling has been reported for three Australian skinks: *Lampropholis delicata*, *Acritoscincus platynota*, and *Carlia schmeltzii* (Doody and Paull, *op. cit.*; Doody and Schembri 2014. Herpetol. Rev. 45:494; Doody and Schembri 2014. Herpetol. Rev. 45:693). Early hatching in response to predation risk might be widespread in lizards in general. Further research should determine the prevalence of early hatching across lizard families to determine if early hatching is an ancestral trait or if it has evolved multiple times within lizards.

***HELODERMA SUSPECTUM* (Gila Monster). PROBABLE COURTSHIP AND MATING BEHAVIOR.** Documentation of reproductive behaviors in wild helodermatid lizards is rare (Beck 2005. Biology of Gila Monsters and Beaded Lizards. University of California Press, Berkeley, California. 211 pp.). Beck (1990. J. Herpetol. 24:54–68) provides detailed descriptions of male-male agonism of *Heloderma suspectum* in nature. However, courtship and mating behaviors in wild *H. suspectum* have not been documented; thus, our understanding of these behaviors is based exclusively on animals in captivity. Courtship and mating in the wild is assumed to take place primarily within burrows or rock shelters (Beck 2005, *op. cit.*). Herein, we report a single observation of probable courtship and mating attempts between two wild *H. suspectum* outside of a rock shelter in the Rincon Mountains, east of Tucson, Arizona, USA (32.2170°N, 110.6757°W, WGS84; 1020 m elev.).

On 17 May 2014, at 0740 h, ERZ observed an adult *H. suspectum* (hereafter, the male) approach a shallow rock shelter that was occupied by another adult *H. suspectum* (hereafter, the female). The male entered the shelter, and < 1 minute later the female left the shelter with the male in pursuit. ERZ observed both individuals for the next 70 minutes, during which time they remained active on the surface. The female walked away from the male repeatedly. In each instance, the male followed in the exact path of the female while tongue-flicking constantly. Occasionally, when the male was < 1 m away from the female, he would follow the circuitous route taken by the female rather than walking directly to her. This behavior suggests the male was following a pheromone trail left by the female (Mason and Parker 2010. J. Comp. Physiol. A 196:729–749).

The pair was in contact 5 or 6 times during the 70 minutes, with each encounter lasting approximately 3–8 minutes. Generally, the male walked around the female before crawling on her and then used his front and hind limbs to alter slightly the position of his body relative to hers (Fig. 1A). The male clasped the base of the female's tail with his hind limb, seemingly rotating her pelvis towards him, a position observed commonly during mating of captive individuals (Fig. 1B; MTS, pers. obs.). During one encounter, the male extruded a hemipenis, but ERZ was unable to determine if he achieved intromission. Coitus under captive conditions lasts for hours (Beck 2005, *op. cit.*), thus it was unlikely in the present case. On 2 or 3 occasions, the male briefly mounted her backwards, with his head above her tail, and tongue-flicked repeatedly (Fig 1C). The female did not appear to be receptive to the male. When the male mounted the female, she flattened her body to the ground, making it difficult for the male to manipulate the positions of their bodies relative to one another. On two occasions, the female responded agonistically towards the male, even biting him as he approached. At 0850 h, the female walked away from the male again, but this time the male pursued her only briefly and then walked in the opposite direction. ERZ ceased observations at 0900 h, when both individuals were on the surface, but separated by >200 m.

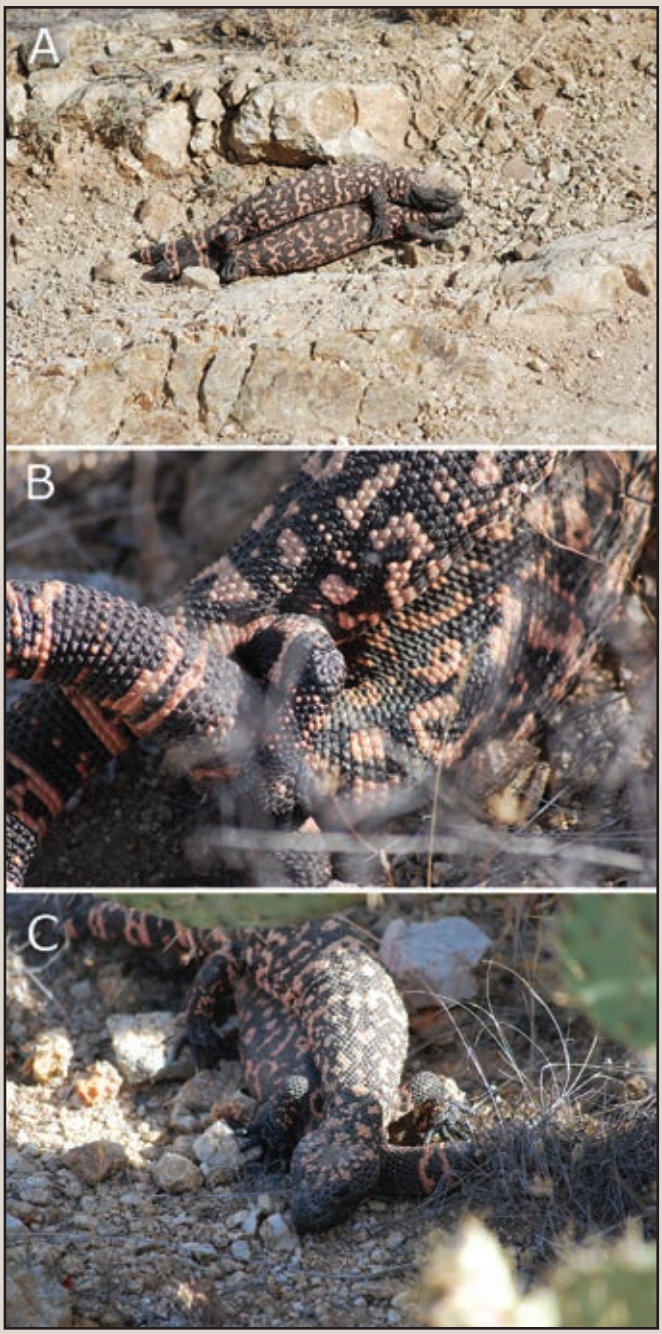

FIG. 1. Probable courtship and mating behaviors between two wild *Heloderma suspectum* in southern Arizona, USA. A) Common position during interactions ("dorsal straddle"), with the male on top of the presumed female. B) Right hind limb of male clasping the base of the female's tail. C) Male on top of the female, with his head positioned above her tail.

Although we were unable to directly verify the sex of the second *H. suspectum* or observe copulation, evidence suggests this was courtship and a failed mating attempt rather than male-male combat. First, the observations were entirely consistent with extensive observations of courting and mating activities of captive *H. suspectum* (Beck 2005, *op. cit.*; MTS and GWS, pers. obs.). Second, most of the observed interactions were not aggressive or typical of combat behaviors observed previously in the wild (Beck 2005, *op. cit.* and references therein). Very few attempts were made by either lizard to dominate the other by

pressing it to the ground (e.g., "head shove," "head raise," or "body twist" described by Beck 1990, *op. cit.*), behaviors that are common in combat rituals. The male repeatedly initiated a "dorsal straddle" (a typical male-male combat behavior; Fig 1A), but the female never did so. In previous observations of male-male combat by *H. suspectum*, both lizards actively participated in dominant behaviors, whereas in the encounter described herein only one lizard, the male, seemed interested in maintaining a superior position or initiating repeated contact. A majority of time was spent with the male in pursuit of the female.

We thank D. E. Swann for reviewing this manuscript.

***LARUTIA TRIFASCIATA* (Three-banded Larut Skink). ENDOPARASITE.** *Larutia trifasciata* is known from parts of the Banjaran Timur and the Cameron Highlands, Malaysia (Grismer 2011. Lizards of Peninsular Malaysia, Singapore and their Adjacent Archipelagos. Edition Chimaira, Frankfurt am Main. 728 pp.). One *L. trifasciata* (SVL = 148 mm) was collected in West Malaysia, Pahang, Cameron Highlands (4.03333°N, 101.36666°E) 25 June 2008 and deposited in the herpetology collection of La Sierra University (LSUHC), Riverside, California as LSUHC 9077. In this note we establish the initial helminth list for *L. trifasciata*.

A midventral incision was made in one *L. trifasciata*. The digestive tract was removed, opened, and the contents were examined for helminths utilizing a dissecting microscope. One nematode was found in the small intestine. It was placed on a microscope slide, cleared in lactophenol, coverslipped, studied under a compound microscope and identified as *Orneoascaris sandoshami*. The sample of *O. sandoshami* was deposited in the Howard W. Manter Laboratory of Parasitology (HWML) University of Nebraska, Lincoln, Lincoln, USA as HWML 64637.

Orneoascaris sandoshami was previously reported in *Megophrys montana* (Megophryidae) (Sprent 1985. An. Mus. Hum. Comp. 60:33–35; Baker 1987. Mem. Univ. Newfoundland, Occas. Pap. Biol. 11:1–325). *Orneoascaris sandoshami* in *L. trifasciata* is a new host record.

***PLESTIODON EGREGIUS ONOCREPIS* (Peninsula Mole Skink). ALBINISM.** On 30 June 2014, we trapped an amelanistic hatchling *Plestiodon egregius onocrepis* (28 mm SVL) along a drift fence in sandhill habitat in Ocala National Forest, Marion Co., Florida, USA (29.3819°N, 81.7929°W, WGS84; 10 m elev.). Albinism has been reported in *P. fasciatus* (Brungs 1960. Copeia 1960:369–370) and *P. reynoldsi* (Catenazzi et al. 2008. Herpetol. Rev. 39:228) but not in *P. egregius*. Most of the head and sides of the body were pink-colored, the dorsum was a paler pink, and the labial scales were white. The short dorsolateral stripes that ran from the pale snout were cream-colored, the lower hind legs and feet were pale orange, and the irises of the eye were red. The tail transitioned from pale pink to light orange, with the distal half being a reddish pink color (the tip was missing). Some internal organs were faintly visible through its venter and sides. A digital color photograph is deposited in the Florida Museum of Natural History (UF 173267).

FIG. 1. Amelanistic (top) and normal (bottom) phenotype *Plestiodon egregius onocrepis* hatchlings from the same site in Ocala National Forest, Marion Co., Florida, USA.

Although albinism is generally considered a deleterious trait because of increased visibility to predators, this may not be the case for this species because of its semifossorial habits. The brown coloration of the normal phenotype blends with fallen leaves, whereas the light coloration of the amelanistic specimen blends with the sand of its upland habitat (Fig. 1). The colorful tail, which probably distracts potential predators, was slightly less vivid in the amelanistic specimen than in another hatchling from the same site (Fig. 1), but there is individual and ontogenetic variation in tail coloration.

KEVIN M. ENGE (e-mail: kevin.enge@myfwc.com), **CODY D. GODWIN**, **PAUL E. MOLER**, and **JONATHAN D. MAYS**, Florida Fish and Wildlife Conservation Commission, 1105 SW Williston Road, Gainesville, Florida 32601, USA.

***PLESTIODON GILBERTI* (Gilbert's Skink). PREDATION.** *Plestiodon gilberti* occurs in a variety of habitats including grasslands, broken chaparral, oak woodlands, and open pine forests (Stebbins and McGinnis 2012. Field Guide to Amphibians and Reptiles of California. University of California Press, Berkeley. 538 pp.). In the Sierra Nevada foothills of California the lizard occurs mainly in the Blue Oak zone and the Blue Oak-Gray Pine zone. Aerial predators, such as Northern Pygmy-Owls (*Glaucidium gnoma*; Sibley 2014. The Sibley Guide to Birds, 2nd ed. Alfred A. Knopf, New York, New York. 599 pp.), are opportunistic

FIG. 1. Northern Pygmy-Owl carrying *Plestiodon gilberti* into a tree cavity.

diurnal predators that takes a variety of mammal, bird, insect, and reptile prey. Documented reptile prey items include Smooth-headed Alligator Lizard (*Gerrhonotus liocephalus*), Eastern Fence Lizard (*Sceloporus undulatus*), Yarrow's Spiny Lizard (*S. jarrovii*), Striped Plateau Lizard (*S. virgatus*), Ornate Tree Lizard (*Urosaurus ornatus*), whiptail lizard (*Aspidoscelis* sp.), and skinks (*Plestiodon* spp.; Holt and Petersen 2000. *In* Poole [ed.], The Birds of North America Online. Cornell Lab of Ornithology, Ithaca, New York; Duncan et al. 2003. Southwest. Nat. 48:218–222). Although *Plestiodon* have been reported previously as prey of the Northern Pygmy-Owl, we provide the first observation, to our knowledge, of the owl predating *P. gilberti*.

On 23 March 2014, a Northern Pygmy-Owl pair was observed on the summit of Black Mountain in eastern Fresno Co., California, USA (37.0130052°N, 119.4523537°W; 1096 m elev.). The female owl was carrying a partially-eaten *P. gilberti*. Eventually she flew into a cavity within a nearby oak (*Quercus* sp.) tree with the skink (Fig. 1). A male Northern Pygmy-Owl followed her into the cavity and they both exited within 5 minutes without the skink. The skink was likely part of a pre-nesting courtship ritual and further observation over the next few weeks revealed that the female had not produced offspring and the skink was likely consumed by the adults.

GARY WOODS, Fresno Audubon Society, P.O. Box 9324, Fresno, California 93791, USA (e-mail: woodshots@earthlink.net); **HOWARD O. CLARK, JR.,** Garcia and Associates, 993 Ezie Avenue, Clovis, California 93611, USA (e-mail: hclark@garciaandassociates.com).

***PODARCIS SICULA* (Italian Wall Lizard). HABITAT, INVASION OF SUBURBAN NEW ENGLAND.** *Podarcis sicula* is a widespread invader in North America (Burke and Ner 2005. Northeast. Nat. 12:349–360). In New York State, multiple populations have been documented on Long Island, most commonly in human-dominated urban and suburban environments (Gossweiler 1975. Copeia 1975:584–585; Burke and Ner 2005, *op. cit.;* Fig. 1A). We documented the first populations of *P. sicula* in Connecticut (Donihue et al. 2014. Herpetol. Rev. 45[4]:661–662), and here describe their habitat use and first evidence for their use of railroad tracks as a conduit for northward invasion.

On 9 July 2014, in response to a photo sent to the Connecticut Department of Energy and Environmental Protection (DEEP), we surveyed multiple sites (Fig. 1B) in Greenwich, Fairfield Co., Connecticut, USA, for *P. sicula*. After talking with homeowners and surveying potential habitat for six hours, we (CMD and MRL) found five individuals spread across three sites (Site 1: three individuals, Site 3: one individual, Site 4: one individual) and were shown a photo of one additional individual at Site 2. All lizards were found in residential backyards within 10 m of railroad tracks, though high-quality habitats further from tracks were also surveyed. At each site lizards were seen basking on stonewalls or in undergrowth in the immediate vicinity of similar perches (Fig. 2A). We also found lizards under miscellaneous plastic and metal objects, and homeowner accounts indicate that lizards often use yard vegetation, metal and wood infrastructure, and garden pots for habitat. On a subsequent visit (29 August 2014) to Site 1, we observed 20 young-of-the-year juveniles, and six adult *P. sicula* after one hour of searching (four juveniles added as specimens to the Yale Peabody Museum YPM HERR.019332–019335). Our observations suggest that *P. sicula* may be moving into New England via railroad tracks and capitalizing on suburban backyards.

According to local landowners, *P. sicula* are seen in abundance (more than five per backyard) and have been present in

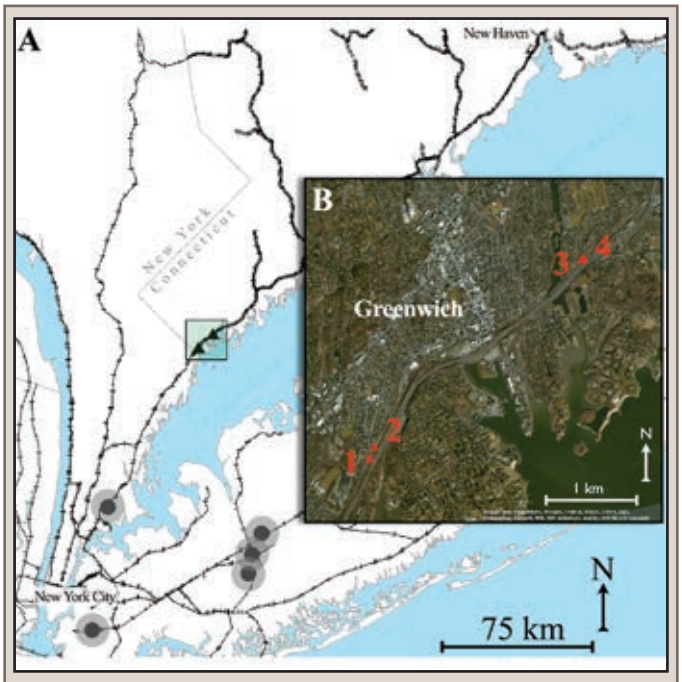

FIG. 1. Map of A) Long Island Sound region with our *P. sicula* sightings in Connecticut (triangles) and previously-reported regions (grey circles) of greater New York City with *P. sicula* populations (Gossweler 1975, *op. cit.*; Burke and Mercurio 2002. Am. Midl. Nat. 147:368–375; Burke and Ner 2005, *op. cit.*; Kolbe et al. 2013. Biol. Invasions 15:775–783. Inset B) details the four new suburban *P. sicula* sites along train tracks in Greenwich, Connecticut, USA.

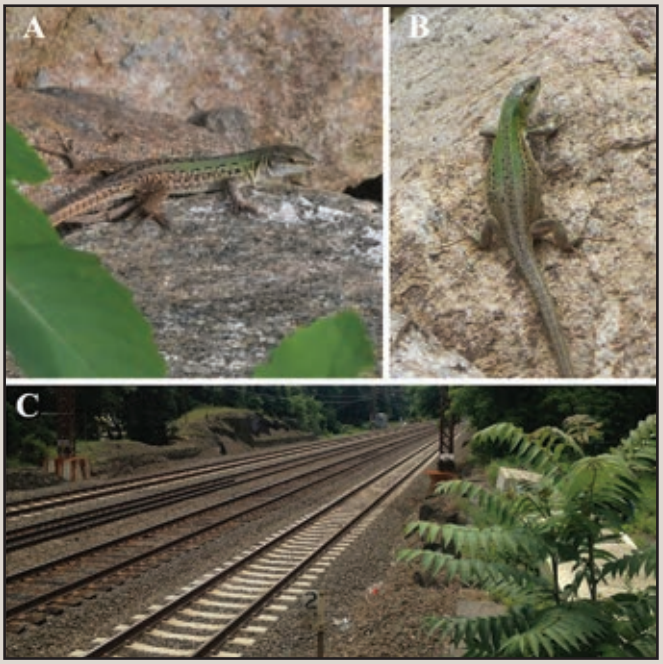

FIG. 2. A) *Podarcis sicula* basking on a rock wall at site 3. This specimen was deposited in the Yale Peabody Museum (YPM HERR.019238). B) A gravid female *P. sicula* at site 3 (photograph courtesy of F. Ceci Jr.). C) Train tracks (adjacent to site A) are the hypothesized avenue of dispersal of *P. sicula* into Connecticut.

this area for multiple years (three years at site 2, two years at site 3) suggesting that they may have reached further north in the state by now. Sites 2 and 3 are separated by 3.04 km of train track, so assuming they were sighted the first summer of their arrival, and train tracks are their conduit, *P. sicula* could very reasonably have already reached Stamford, a dense urban area. Although it is possible that the Connecticut *P. sicula* populations are a result of recent introductions, we think it much more likely that railroads act as a dispersal route from New York City; closely related lacertids are known to use tracks in their native European range (Kühnel 2008. *In* Mitchell et al. [eds.], Urban Herpetology, pp. 171–174. Society for the Study of Amphibians and Reptiles, Salt Lake City, Utah). Existing New York populations are within close proximity of train tracks leading directly to these Connecticut backyards (Fig. 1a). As this represents *P. sicula*'s northernmost occurrence, how they survive the cold New England winters is an important question. The railroad tracks also provide a potential explanation as portions of track are heated throughout the winter to prevent snow and ice buildup. Burrowing in the scree under these heated portions may provide protection from both predators and the elements. Urban areas are also well-documented heat-islands, potentially also providing warm refuges in winter. The extent to which species like *P. sicula* are adapting to live in urban and suburban environments is an emerging question for future study (Donihue and Lambert 2014. AMBIO 44:194–203).

We thank Jenny Dickson at Connecticut Department of Energy and Environmental Protection for her support, along with Frank Ceci Jr. and three additional anonymous landowners for allowing us to survey their properties. Specimen collection was authorized under Connecticut permit number 0116019 and Yale University IACUC protocol number 2012-10681.

***SCELOPORUS JARROVII* (Yarrow's Spiny Lizard) and *SCELOPORUS POINSETTII* (Crevice Spiny Lizard). PREFERRED BODY TEMPERATURE.** Data on preferred body temperature (T_p) is quite rare (Sinervo et al. 2010. Science 328:894–899). According to Huey (1982. *In* Gans and Pough [eds.], Biology of the Reptilia, Vol. 12, Physiology C, pp. 25–91. Academic Press, New York) measurement in a laboratory thermal gradient under standard conditions is required. The T_p that a lizard voluntarily selects in a laboratory thermal gradient provides a reasonable estimate of what a lizard would attain in the wild with a minimum of associated costs in absence of constraints (biotic and abiotic factors) for thermoregulation (Huey and Slatkin 1976. Q. Rev. Biol. 51:363–384; Pough and Gans 1982. *In* Gans and Pough [eds.], Biology of Reptiles, Vol. 12, pp. 17–23. Academic Press, New York). *Sceloporus jarrovii* and *S. poinsettii* are geographically widespread viviparous lizards that exhibit considerable variation in habitats occupied (Lemos-Espinal and Smith 2007. Anfibios y Reptiles del Estado de Chihuahua, México /Amphibians and Reptiles of the State of Chihuahua, México. UNAM-CONABIO. México, D.F. 613 pp.; Lemos-Espinal and Dixon 2013. Amphibians and Reptiles of San Luis Potosí. Eagle Mountain Publishing, Eagle Mountain, Utah. 312 pp.). There have been several reports detailing thermal ecology in *S. jarrovii* and *S. poinsettii* in different environments (Andrews 1998. J. Therm. Biol. 23:329–334; Gadsden and Estrada-Rodríguez 2007. Southwest. Nat. 52:600–608); nevertheless, data on T_p of these two species are unusual (Mathies and Andrews 1997. Funct. Ecol. 11:498–507; Lara-Reséndiz et al. 2014. Rev. Mex. Biol. 85:744–753). Here, we describe thermal preferences in sympatric species *S. jarrovii* and *S. poinsettii* under laboratory conditions.

During October 2012, we conducted fieldwork in the canyon of Las Piedras Encimadas (25.7022°N, 103.7080°W, WGS84; 1425 m elev.), 25 km NW Gomez Palacio, Durango, Mexico. Vegetation was dominated by *Agave lechuguilla*, *Acacia greggii*, *Opuntia leptocaulis*, and *Jatropha dioica*. Throughout the study site, rock faces with crevices were numerous. The data presented are based on 10 adults (> 60.0 mm SVL) of *S. jarrovii* and 10 adults (> 77.0 mm SVL) of *S. poinsettii* captured by noose.

All lizards were placed in a laboratory thermal gradient to obtain the T_p range. The thermal gradient consisted of a wooden shuttle box of 150 x 100 x 80 cm (length, width, and height) divided into ten tracks with insulation barriers to prevent behavioral influence of adjacent lizards, and filled with 2–3 cm of rocky substrate. The shuttle box was housed in a room with air conditioning at a constant temperature of 20°C. At one end, and at the center of the box, lamps were placed at different heights to generate a thermal gradient from 20 to 50°C. The T_p of lizards was measured every hour from 0900 until 1800 h (activity period) using a digital thermometer Fluke model 51-II. The 25% and 75% quartiles of each species' T_p range (T_{p25} and T_{p75}) were calculated to obtain the lower and upper limit (Van Damme et al. 1990. Oikos 57:61–67; Herts et al. 1993. Am. Nat. 142:796–818). After laboratory experiments, all lizards were released at their capture sites. We applied a nonparametric Kruskal-Wallis one-way test to analyze differences between all measurements of body temperature in the laboratory and we used a Mann-Whitney Rank test to analyze the differences between species.

There were no statistically significant differences between measurements of temperature (H_6 = 9.0, P = 0.17) or between species (U = 5.842, P = 0.41). Mean T_p of *S. poinsettii* was 32.9°C (SE = 0.70, range = 21.7–40.0°C; N = 34). Interquartile of 25% and 75% was 30.6°C and 35.5°C, respectively. On the other hand, for *S. jarrovii*, mean of T_p was 33.6°C (SE = 0.40, range = 25.1–39.8°C; N = 47). Interquartile of 25% and 75% was 32.4°C and 35.6°C, respectively. The preferred body temperature of *S. jarrovii* and *S. poinsettii* were very similar to each other, and temperatures are similar to those previously registered for other closely related species of *torquatus* group as *S. torquatus*, *S. serrifer*, *S. minor*, *S. mucronatus*, *S. ornatus*, and *S. cyanostictus* (Andrews 1998, *op. cit.*; Sinervo et al. 2010, *op. cit.*).

These results suggest that *S. poinsettii* and *S. jarrovii* can be considered eurythermic species due to their wide range of T_p. Future research should evaluate the species thermal efficiency by monitoring mean thermal requirements and microhabitat temperatures across its distribution for understanding effects of global warming on these geographically widespread lizards.

***SCELOPORUS SINIFERUS* (Long-tailed Spiny Lizard). BIPEDALISM.** Bipedal locomotion has been studied in a wide array of lizard species representing numerous families (e.g., Snyder 1952. Copeia 1952:64–70; Snyder 1962. Am. Zool. 2:191–203; Irschick and Jayne 1999. J. Exper. Biol. 202:1047–1065). However, reports for bipedalism, typically regarded as a flight response to predation or to aid in foraging, are scarce in the literature for *Sceloporus*, having been reported only for *S. undulatus* (*sensu lato*; Snyder 1952, *op. cit.*), *S. woodi* (Tucker and McBrayer 2012. Biol. J. Linn. Soc. 107:813–823), and *S. malachiticus* (Kohlsdorf and Biewener 2006. J. Zool. 270:359–371). All three reports were filmed in laboratory studies. The first two species are members of the *undulatus* group and the latter is a member of the *formosus* group (Wiens et al. 2010. Mol. Phyl. Evol. 54:150–161). Here we report on bipedal locomotion in the field in a member of the *siniferus* group, *S. siniferus*, employed in response to two distinct biological situations: 1) in flight to evade capture and 2) in male-male combat.

On 26 July 2008, two of us (JDS and WHM) observed an adult male *Sceloporus siniferus* run bipedally at a site ca. 10 km north (by air) of San Jeronimito, Guerrero, Mexico (17.6580°N, 101.3330°W, WGS84). The lizard was being pursued for capture and subsequent data collection. It ran along the ground for an extended distance, clearly on its hind limbs, into dense vegetation and evaded our capture. This escape behavior was observed again in this species the following day on 27 July at Parque Ecológico Aztlán in Ixtapa, Guerrero, Mexico (17.6793°N, 101.6223°W; WGS84).

On 12 June 2012, one of us (DKH) was conducting staged territorial intrusions to study male-male aggression in *Sceloporus siniferus,* in the southern portion of Parque Nacional Huatulco, ca. 3 km W of Huatulco, in coastal Oaxaca, Mexico (15.7556°N, 96.1550°W; WGS84). The focal animal, a free-ranging adult male *Sceloporus siniferus* ran bipedally across a dirt road to the location of the stimulus male (intruder) that had been placed at 2 m distant from the focal male along the edge of the vegetation along the road. The males then engaged in aggressive signaling behavior, followed by physical contact (biting). This behavioral response of the focal male is consistent with territorial defense, which we were studying during the first part of the breeding season for this species.

The morphology of *S. siniferus* is such that bipedalism is perhaps not surprising; the hind limbs and feet are extremely well-developed and proportionately large for a species of this genus. Further, the tail is very long (at least twice the length of the body in males) and likely serves as a counter-balance during bipedal locomotion.

***SCELOPORUS UNDULATUS* (Eastern Fence Lizard). NOVEL VENTRAL ORNAMENTATION.** During the breeding season, adult females of many species in the family Phrynosomatidae express an orange-colored patch (or patches) (Cooper and Greenberg 1992. *In* Gans and Crews [eds.], Biology of the Reptilia, Vol. 18, Hormones, Brain, and Behavior, pp. 298–422. University of Chicago Press, Chicago, Illinois). These patches likely reflect the suites of physiological changes occurring during the onset of the reproductive season (Cooper and Burns 1987. Anim. Behav. 35:526–532), and may therefore serve as a signal of receptivity to a potential mate. Despite the commonality of this social signal in Phrynosomatidae, within the genus *Sceloporus*, the development of orange-colored patches by a female has only been documented in a single species, the Striped Plateau Lizard (*S. virgatus,* Vinegar 1972. Copeia 1972:660–664; Weiss et al. 2012. Comp. Biochem. Physiol. B. 161:117–123). In *S. virgatus*, paired orange patches develop on the throat of a female lizard during vitellogenesis and their expression peaks during ovulation, followed by a period of fading as eggs mature (Weiss et al. 2012, *op. cit.*). Here we document a novel case involving the expression of paired orange patches on the ventral surface of the abdomen, and not the throat, of a gravid adult female *S. undulatus*.

S. undulatus is a medium-sized lizard that ranges throughout the central and eastern United States from southwest Utah to the east coast (adult SVL in Ohio, 75 ± 0.8 mm [mean ± SE], Tinkle and Ballinger 1972. Ecology 53:570–584). Females are receptive from mid-April to late June (Tinkle and Ballinger 1972, *op. cit.*). Males and females of *S. undulatus* are sexually dichromatic (Cooper and Burns 1987. Anim. Behav. 35:526–532). Whereas male *S. undulatus* consistently exhibit blue and black throat and ventral patches, female *S. undulatus* express either no ventral coloration or may display muted blue throat and ventral patches (Cooper and Burns 1987, *op. cit.*).

We captured a female *S. undulatus* by noose pole on an oak (*Quercus* sp.) snag in the Vinton Furnace Experimental Forest in Vinton Co., Ohio (39.202°N, 82.3914°W) on 26 April 2014 at 1137 h. The specimen was large and visibly gravid (SVL = 78.5 mm, mass = 21.5 g), and exhibited a pair of orange patches, each extending approximately half of the distance between her fore- and hind limbs, on her ventral surface. The size and color of these patches did not change in the 48-h period from capture to release

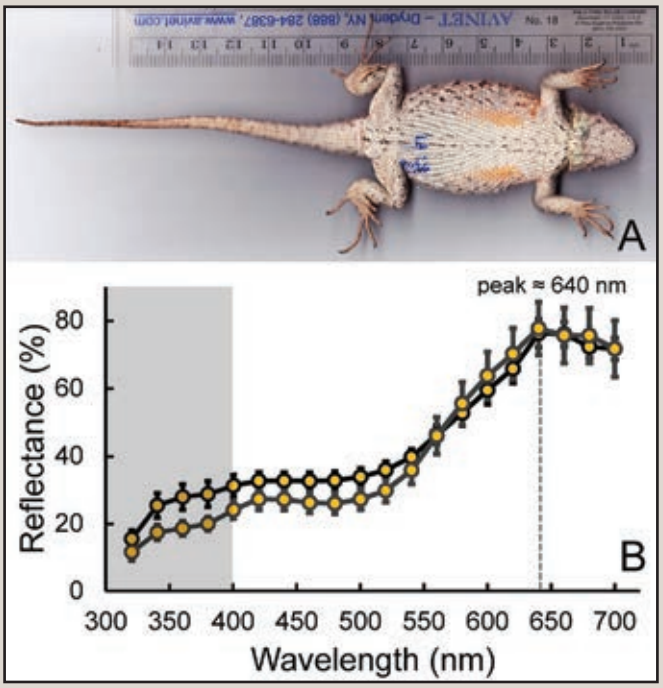

FIG. 1. Ventral surface of the adult female *Sceloporus undulatus* (A) and the percent reflectance (B) of each orange patch on her abdomen, averaged at 20 nanometer (nm) intervals (black line, left patch; grey line, right patch). Points in (B) are mean ± 1.0 standard deviation. Shaded light grey area references the wavelength range of ultraviolet light (320–399 nm), and the dashed vertical line indicates the average peak reflectance across both patches (≈ 640 nm).

back at the field site. We transported the female to our lab facility at Ohio University for processing. Photo documentation of these ventral patches was obtained by scanning the ventral surface of the female lizard in a Canon LiDE flatbed scanner (Canon, Melville, NY, USA). The size (in pixels) of the left and right orange patch was then estimated using the polygon tool in the program ImageJ version 1.44p (http://imagej.nih.gov/ij/). We converted the area of these polygons from pixels to mm^2 with the aid of a ruler affixed to the plate. The average area of these patches was 57.1 mm^2 (left patch: 55.6 mm^2, 35 scales; right patch: 58.6 mm^2, 36 scales) (Fig. 1).

We measured the spectral profile (reflectance, %) of each orange patch using an Ocean Optics USB2000-UV-VIS spectrometer with a pulsed fiber-optic light source (Ocean Optics Worldwide, Dunedin, FL, USA). We took three readings (integration time = 295 ms, boxcar correction = 10) total at cranial, middle, and caudal regions of each patch. Our reflectance data (in 0.3 nm increments) were obtained across a range of wavelengths that encompass the visible range of a lizard (320–700 nm). We then averaged the three readings for each patch and summarized their output in 20-nm increments. Reflectance spectra from these patches are consistent with orange coloration (peak wavelength ≈ 640 nm). The reflectance curves of these patches are also similar in form as published curves of the orange throat patches of *S. virgatus* (Weiss et al. 2012, *op. cit.*). We also note similar degree of reflectance in the ultraviolet range (ca. 30%).

To our knowledge, this is the first documented case of atypical ventral coloration in a female *Sceloporus* species. Data for *S. virgatus* suggest that orange coloration is drosopterin-based, and not derived from carotenoids in the animal's diet (Weiss et al. 2012, *op. cit.*). Further work is needed to elucidate the physiological basis, functional role, and behavioral significance of this novel ornament in female *S. undulatus*, including its prevalence in other females of the species.

ANTHONY L. GILBERT, 107 Irvine Hall, Department of Biological Sciences, Ohio University, Athens, Ohio 45701, USA (e-mail: ag499412@ohio.edu); **MATTHEW S. LATTANZIO,** 1004 Forbes Hall, Department of Organismal and Environmental Biology, Christopher Newport University, Newport News, Virginia 23606, USA (e-mail: matthew.lattanzio@cnu.edu).

***SCINCUS SCINCUS* (Sandfish Skink). ENDOPARASITES.** *Scincus scincus* is widely distributed in the Middle East, North Africa, Niger, and Nigeria (Bar and Haimovitch 2011. A Field Guide to Amphibians and Reptiles. Herzilya, Israel. 245 pp.). Gamil (2012. World J. Zool. 7:65–74) reported *Ophiotaenia* sp. in *S. scincus* from Sinai, Egypt. The purpose of this note is to add to the helminth list of *S. scincus* as part of an ongoing survey of helminths of Middle Eastern Lizards.

Two adult *S. scincus* were collected and deposited in the Field Museum of Natural History (FMNH), Chicago, Illinois as FMNH 63941, collected in Egypt, Giza, vicinity of Cairo (30.0500°N, 31.2333°E) November 1960 and FMNH 66312 collected in Egypt, Giza, Abu Rabash (30.0319°N, 31.0750°E) February 1951. A mid-ventral incision was made and three larval nematodes were recovered from the body cavity, 2 in FMNH 63941 and 1 in FMNH 66312. Nematodes were cleared in lactophenol on a microscope slide, coverslipped, studied under a compound microscope and identified as larvae of *Physocephalus* sp. Voucher helminths were deposited in the Howard W. Manter Laboratory of Parasitology (HWML), University of Nebraska, Lincoln, USA, as HWML 64636.

Goldberg et al. (1994. J. Wild. Dis. 30:274–276) reported larvae of *Physocephalus* sp. occurred in the gastric mucosa of *Sceloporus cyanogenys* (formerly as *S. serrifer*) from Texas, USA, which cause focal destruction of gastric glands. Adult nematodes of *Physocephalus sexalatus* occur in the stomachs of mainly wild and domestic pigs (Anderson 2011. Nematode Parasites of Vertebrates, Their Development and Transmission. CABI Publishing, Wallingford, Oxfordshire, U.K. 650 pp.). Infective larvae have been recovered from tissues of twenty different genera of dung beetles (Anderson 2011, *op. cit.*). Lizards that habitually feed on dung beetles would likely become infected. As development to the adult *Physocephalus* does not occur in lizards, they are best considered as paratenic (transport hosts). *Physocephalus* sp. in *Scincus scincus* is a new host record.

We thank A. Resetar (FMNH) for permission to examine *S. scincus*.

STEPHEN R. GOLDBERG, Whittier College, Biology Department, Whittier, California 90608, USA (e-mail: sgoldberg@whittier.edu); **CHARLES R. BURSEY** Pennsylvania State University, Department of Biology, Shenango Campus, Sharon, Pennsylvania 16146, USA (e-mail: cxb13@psu.edu).

***VARANUS PANOPTES* (Yellow-spotted Monitor). DIET.** Determining the diet of large carnivorous animals is important because those species can have considerable regulatory impacts on the food web. However, dietary analysis based on dissections, stomach flushing, and scat can bias dietary information because larger prey are eaten infrequently. It is thus critical to make observations of predation in nature to build a more complete picture of dietary breadth. Herein we report on a case of apparent predation by *Varanus panoptes* on *V. scalaris* (Spotted Tree Monitor) from northwestern Australia.

At ~1500 h on 14 February 2014 we captured an adult female *V. panoptes* in savannah woodland about 150 m from the Margaret River in Western Australia. The animal had hidden in grass thickets upon our approach, but was spotted and captured by hand for a study of the species' spatial ecology. Immediately upon capture the lizard regurgitated an adult *V. scalaris* and five large caterpillars (Sphingidae). The regurgitated lizard was covered in saliva but was not degraded, indicating recent consumption. Protruding from the mouth of the *V. scalaris* was one of the five caterpillars; the other four caterpillars were lying near the *V. scalaris*. All prey items were dead. The *V. panoptes* was taken to the field laboratory and the *V. scalaris* and caterpillars were preserved in 80% ethanol. The *V. scalaris* weighed 94 g, which was 7.3% of the body mass of the *V. panoptes* (1285 g).

In our judgment the *V. panoptes* had consumed the *V. scalaris* within a few minutes or hours of capture, based on the immaculate condition of the latter. Although we cannot eliminate the possibility that the regurgitated lizard was scavenged, predation is more likely due to the condition of the prey. Moreover, *V. panoptes* consumes other species of monitor lizards (Shine 1986. Herpetologica 42:346–360; Christian 1995. Herpetol. Rev. 26:146; Rhind and Doody 2011. Herpetofuna 41:64–65; Doody et al. 2012. Herpetol. Rev. 43:491–492). The caterpillar in the mouth of the *V. scalaris* probably reflected foraging by that lizard; however, the other four caterpillars, which were also in very good condition, may have been eaten and regurgitated by either the *V. scalaris* or the *V. panoptes*. The caterpillars were conspicuously abundant on ground level vegetation during the time of our observation. Regardless, our observation spans three trophic levels, providing insights into the community ecology in the riparian zone of the tropical savannah woodland. It also suggests that *V. panoptes* may regulate *V. scalaris*. When the invasive Cane Toad (*Rhinella marina*) invaded other parts of northern Australia, the ~90% reduction in *V. panoptes* (due to lethal toxic ingestion of toads) caused increases in some of its prey (Doody et al. 2006. Wildl. Res. 33:349–354; Doody et al. 2009. Anim. Conserv. 12:46–53; Doody et al. 2013. Biol. Inv. 15:559–568). It is possible that the same mesopredator release will occur with *V. scalaris* when toads arrive at our site within the next few years. However, *V. scalaris* can also suffer lethal toxic ingestion of cane toads (S. Doody, S. Clulow, and C. McHenry, unpubl. data). Thus, the complex effects of Cane Toads may make predictions of their impacts difficult in this system.

SQUAMATA — SNAKES

***AGKISTRODON PISCIVORUS* (Cottonmouth). PREDATION.** *Geococcyx californianus* (Greater Roadrunner) is a generalist predator well known for its occasional habit of preying on venomous reptiles. However, to our knowledge *Agkistrodon piscivorus* has yet to be documented as a prey item for this species (Ernst and Ernst. 2003. Snakes of the United States and Canada. Smithsonian Books, Washington, DC. 680 pp.). On 19 September 2014, one of us (TN) observed a *G. californianus* kill and consume a juvenile *A. piscivorus* in the Hagerman National Wildlife Refuge, Sherman, Texas (Fig. 1) on a caliche road approximately 130 m from the nearest body of water. Over the course of 5–6 min, the *G. californianus* pecked at and flung the *A. piscivorus* around until it was unresponsive. At this point, the *G. californianus* swallowed the snake.

FIG. 1. *Geococcyx californianus* (Greater Roadrunner) preying on a juvenile *Agkistrodon piscivorus* in the Hagerman National Wildlife Refuge, Sherman, Texas, USA.

TREY NEAL, 1600 North Saint Charles Ave, Pilot Point, Texas 76258, USA (e-mail: trey@natureswildscapes.com); **DAVID A. STEEN**, Alabama Natural Heritage Program, 1090 South Donahue Drive, Auburn, Alabama 36832, USA.

***AHAETULLA PRASINA* (Asian Vinesnake). DIET AND FEEDING BEHAVIOR.** At 0830 h on the morning of 2 October 2013 on the grounds of Ubud View Bungalows hotel in Ubud, Bali, (8.5167242°S, 115.2647486°E, datum WGS84; elev. 20 m), we observed a juvenile *Ahaetulla prasina* (total length ca. 60 cm) falling to the ground with a gecko (*Hemidactylus platyurus*; total length ca. 10 cm) seized in its jaws by the nape (Fig. 1). The snake and gecko both fell from a height of ca. 3 m from the overhead canopy of a palm tree on to a stone pavement, where they struggled before the snake began retreating backwards dragging its prey away from the exposed area. First it moved ca. 1.5 m across the pavement, then up a small wall ca. 0.5 m high and continued ca. 1 m across a flower bed. During this time, the gecko appeared to have lost most function in its forward and hind limbs. The snake held on to the gecko and continued chewing movements, likely increasing venom delivery (Whitaker and Captain 2008. Snakes of India, the Field Guide. Draco Books, Chengalpattu, India. 385 pp.). After ca. 40 min, the gecko appeared to be completely immobilized and the snake proceeded to swallow it headfirst while continuing to move in a backwards motion up the base of the tree. After reaching ca. 0.5 m up the base of the tree, the snake stopped swallowing and released the gecko having only achieved swallowing the head. The gecko was large in proportion to the snake, but another possibility is that the snake abandoned its prey in response to disturbance from us.

Although vine snakes are typically arboreal they have been observed consuming large prey on the ground, possibly falling after striking prey (Miranda et al. 2013. Herpetol. Notes 6:187–188). Falling from the tree would likely have placed the snake in a situation where it was at an increased risk of predation. Despite

FIG. 1. *Ahaetulla prasina* subduing *Hemidactylus platyurus*, Ubud, Bali.

our presence, the snake did not abandon its prey, but instead, retreated across the pavement backwards while still holding on to its meal. The snake used its tail to pull and guide its body backwards by waving its tail around in a reaching fashion until it found something to grip on to, while dragging the gecko with it. The snake continued to retreat using this technique as it climbed backwards up the small wall, down to a flower bed, and across to the base of a palm tree. Retreating backwards allowed the snake to carry its prey to safety while keeping potential predators, us, in view. Although snakes sometimes retreat during feeding, we deem that the distance moved by this snake of this size was exceptional. This may be a trait specific to specialized arboreal snakes, but can be difficult to observe due to their cryptic nature in the canopy. Also, no evidence was found in the literature of *Hemidactylus* specifically in the diet of *Ahaetulla*; therefore, *H. platyurus* appears to be new diet record for *A. prasina*.

We thank Adam Radovanovic, Rob O'Sullivan, Konrad Mebert, Jackson Shedd, Indraneil Das, and Steve Gorzula for correspondence and advice, Ron Lilley for photographic identification of the gecko, and Jesus Rivas and Rob Gandola for advice and critical revision of this manuscript.

JOHN P. DUNBAR, Alistair Reid Venom Research Unit, Department of Parasitology, Liverpool School of Tropical Medicine, Liverpool L3 5QA, United Kingdom (e-mail: john.dunbar@lstmed.ac.uk); **TERESA M. DUNBAR**, Bracklin road, Edgeworthstown, County Longford, Ireland (e-mail: teresa.dunbar.2014@nuim.ie).

***AHAETULLA PRASINA* (Oriental Whipsnake). REPRODUCTION.** *Ahaetulla prasina* is widely distributed in South-east Asia; its range includes Myanmar, Thailand, Laos, Cambodia, Vietnam, Peninsular Malaysia, Borneo, Java, Bali, northeastern India, Bangladesh, China and the Sulu Archipelago (Das 2010. A Field Guide to the Reptiles of South-East Asia. New Holland Publishers, London. 376 pp.). We know of no published information on reproduction of male *A. prasina*. In this note, we present information on the minimum size for maturity in male *A. prasina*.

Ten adult male *A. prasina* were examined (mean SVL = 883.0 mm ± 69.6 SD, range = 784-963 mm) and one juvenile male (SVL = 747 mm) from Peninsular Malaysia collected by LLG during 2002-2005, 2011 and deposited in the herpetology collection (LSUHC) of La Sierra University, Riverside, California 92515, USA (by state): Johor, LSUHC 5737, 6402; Kedah, LSUHC 10597; Pahang, LSUHC 4491, 4798, 4551, 5432, 5488, 5507; Penang, LSUHC 8382. The juvenile male (LSUHC 7589) was from Kedah state. The lower part of the body cavity was opened and the left testis was removed, embedded in paraffin, histological sections cut at 5 µm and stained by Harris hematoxylin followed by eosin counterstain. Histology slides are deposited in LSUHC. Two stages were noted in the testicular cycle: 1) regressed, seminiferous tubules are reduced in size, spermatogonia and interspersed Sertoli cells are present; 2) spermiogenesis, seminiferous tubules are lined by sperm or clusters of metamorphosing spermatids.

One juvenile male from August (LSUHC 7589) exhibited a regressed testis. Number of mature males (spermiogenesis) by month were: January (N = 1), March (N = 1), July (N = 6), August (N = 1), October (N = 1). The presence of the smallest (spermiogenesis) mature male (LSUHC 10597) at 784 mm SVL and a subadult male with a regressed testis at 747 mm SVL (LSUHC 7589) suggests male *A. prasina* from Peninsular Malaysia mature at ca. 780 mm SVL. The presence of spermiogenesis during widely separated months suggests *A. prasina* males exhibit a polyestrous reproductive cycle with continuous sperm production (*sensu* Saint Girons 1982. Herpetologica 38:5–16).

STEPHEN R. GOLDBERG, Whittier College, Department of Biology, Whittier, California 90608, USA (e-mail: sgoldberg@whittier.edu); **LEE GRISMER**, La Sierra University, Department of Biology, Riverside, California 92515, USA (e-mail: lgrismer@lasierra.edu).

***APOSTOLEPIS CEARENSIS* (Burrowing Snake). DIET.** *Apostolepis cearensisis* is a fossorial snake distributed in the semiarid Caatinga (Lema and Renner 2007. Biociências 15:126–142) and Cerrado biomes in Brazil (Lema and Renner 2012. Neotrop. Biol. Conserv. 7:144–147). Very little is known about its biology and behavior (Mesquita et al. 2009. Pap. Avul. Zool 53:99–113; Mesquita et al. 2013. Herpetol. Rev. 40:440). Herein, we provide a diet record from an *A. cearensis* collected in March or April 2013 at São Gonçalo do Amarante municipality (3,544028°S, 39,126694°W, datum WGS 84; elev. 28 m), Ceará state, Brazil. Dissection of the adult female *A. cearensis* (SVL = 47.0 cm) revealed an adult *Leposternon polystegum* (8.0 g) in the stomach (Fig. 1). Both the *A. cearensis* and the *L. polystegum* specimens were deposited at

FIG. 1. Adult female *Apostolepis cearensis* and its prey, a *Leposternon polystegum*.

Coleção Herpetologica da Universidade Regional do Cariri (URCA-H 8942 and 8986). Species of the genus *Apostolepis* have diverse diets composed mainly of amphisbaenians, small snakes, and invertebrates (Lema 2001. Cuad. Herpetol. 15:29–43; Lema and Renner 2006. Cienc. Mov. 8:13–18). For *A. cearensis*, the snake *Tantilla melanocephala* has been reported as prey (Mesquita et al. 2009, *op. cit.*; Mesquita et al. 2013, *op. cit.*).This is the first record of *L. polystegum* as prey of *A. cearensis*.

We are grateful to Fundação Cearense de Apoio ao Desenvolvimento Científico e Tecnológico – FUNCAP for are search fellowship to RWA (process BPI-0067-000060100/12) and Coordenação de Aperfeiçoamento de Pessoal de Nível Superior – CAPES for master fellowship to MCS.

Antonio Luiz, 1161, Bairro do Pimenta, CEP 63105-100, Crato, Ceará, Brazil; Programa de Pós-Graduação em Bioprospecção Molecular, Departamento de Ciências Físicas e Biológicas, Laboratório de Herpetologia, Universidade Regional do Cariri (URCA).

***BITIS CAUDALIS* (Horned Adder). FOG WATER HARVESTING.** Many species of reptiles are capable of drinking rainfall that has collected on their scale surfaces, and this method of water acquisition is likely to be particularly important for those species occurring in xeric environments (Repp and Schuett 2008. Southwest. Nat. 53:108–114; Glaudas 2009. Southwest. Nat. 54:518–521). Additionally, in arid environments where rainfall is scarce, some organisms can harvest and utilize fog or dew from their body surfaces (Malik et al. 2014. Bioinspir. Biomim. 9:1–15). For example, the Namib Desert endemic *Bitis peringueyi* (Peringuey's Adder) is a specialized sand-dwelling viperid that is known to harvest fog water that has condensed on its scales (Robinson and Hughes 1978. Ann. Transvaal Mus. 31:189–193). *Bitis caudalis* is a more widely distributed viperid ranging throughout southern Africa and also occurs extensively throughout the Namib Desert. This species has been photographed drinking water from its skin, but whether this behavior was documented *in situ* and the source of the moisture, are both unknown (Greene 1997. Snakes, the Evolution of Mystery in Nature. Univ. California Press, Berkeley. 351 pp.). Here we report on an observation of *B. caudalis*, drinking condensed fog water directly from its body surface.

At 0710 h on 1 July 2014 at the Gobabeb Research and Training Centre, Namibia (23.56027°N, 15.04037°E, WGS84; elev. 406 m) we observed a small juvenile *B. caudalis* loosely coiled on bare gravelly substrate at the edge of a gravel road. At this time a fog event had occurred depositing 0.9 liters m^{-2} of fog water as measured by vertical standard fog collectors of 1 m^2. The ground surface temperature where the snake was located was 14.3°C and the air temperature 10 mm above the surface was 13.3°C. Though temperatures were cool, the snake was in the open at least 1 m from the nearest rocky shelter and was actively imbibing water that had condensed on its scales (Fig. 1). Although to our knowledge this represents the first unequivocal instance of fog water use in *Bitis caudalis*, we do not think this behavior is unusual, but simply under-reported for this and other species living in fog deserts. We thank Gillian Maggs-Kölling and Theo Wassenaaar as well as the Brain Function Research Group at the University of the Witwatersrand for support, and the Namibian Ministry of Environment and Tourism for permission to work in the Namib-Naukluft National Park. Novald Iiyambo kindly provided the fog water measurements.

IAN W. MURRAY, Brain Function Research Group, School of Physiology, Faculty of Health Sciences, University of the Witwatersrand, Parktown, 2193, Johannesburg, South Africa (e-mail: Ian.Murray@wits.ac.za); **ELNA IRISH**, Gobabeb Research and Training Centre, P.O. Box 953, Walvis Bay, Namibia.

***BOTHROPS ASPER* (Fer-de-Lance). DIET AND FEEDING BEHAVIOR.** *Bothrops asper* is widely distributed throughout Central and northern South America and is considered a dietary generalist, with a diet primarily consisting of rodents, birds, lizards, and anurans (Sasa et al. 2009. Toxicon 54:904–922). Many reports of birds consumed pertain to "unidentified passerines," but *Volantinia jacarina* (Blue-Black Grassquit) and *Cantorchilus nigricapillus* (Bay Wren) have been specifically reported (Sasa et al., *op. cit.*). I observed a *B. asper* preying upon a *Eucometis penicillata* (Gray-headed Tanager) which was following a swarm of army ants (*Eciton* sp.) in Parque Nacional Soberanía near Gamboa, Panamá on 11 March 2013 at 1100 h. I encountered the army ant swarm, which was being followed by several species of birds including *E. penicillata*, *Hylophylax naevioides*, and *Microcerculus marginatus*, near Quebrada Juan Grande off the Pipeline Road. The snake captured the tanager as it came to the ground to forage on insects disturbed by the ant swarm. The bird was consumed head-first (Fig. 1). As I did not see the snake before it captured the tanager, I cannot determine whether the snake was actively foraging around the ant swarm as well or opportunistically encountered it. I observed the snake for approximately 15

PHOTO BY IAN W. MURRAY

FIG. 1. Juvenile *Bitis caudalis* drinking fog water condensed on its body.

FIG. 1. Gray-headed Tanager (*Eucometis penicillata*) that fell prey to a *Bothrops asper* (Fer-de-Lance) while foraging for invertebrates flushed by army ants in Parque Nacional Soberanía, Panamá.

min in which time it had only consumed the bird up to its head (Fig. 1). As the sparse previous reports of *B. asper* predation on birds do not pertain to species that typically follow ant swarms, this observation represents a unique account of a feeding behavior by this species.

I thank J. Ray for confirming the identification of the snake from photos and the Smithsonian Tropical Research Institute for support to work in Panamá. This encounter was observed incidentally during unrelated field work and no organisms mentioned in this note were handled, collected, or disturbed in any way.

ERIC K. MOODY, Arizona State University School of Life Sciences, 427 E. Tyler Mall, Tempe, Arizona 85287, USA; e-mail: ekmoody@asu.edu.

***COLUBER FLAGELLUM* (= *MASTICOPHIS FLAGELLUM*) (Coachwhip). GENERAL ECOLOGY.** *Coluber flagellum* (= *Masticophis flagellum*) is a medium-sized colubrid with a broad geographic distribution and found in a wide variety of habitats, including those in the Chihuahuan Desert (Ernst and Ernst 2003. Snakes of the United States and Canada. Smithsonian Institution Press, Washington, D.C. 668 pp.). However, little is known regarding life history characteristics of this species, such as home range and movement rate, habitat, and body temperatures (Secor 1995. Herpetol. Monogr. 9:169–186; Johnson et al. 2007. Southeast. Nat. 6:111–124; Dodd and Barichivich 2007. Florida Sci. 70:83–94; Steen et al. 2007. Herpetol. Rev. 38:90) with no information from populations found in its western distribution. Herein, we provide information on home range, movement rate, habitat and microhabitat, and body temperatures of a single *C. flagellum* in the northern Chihuahuan Desert.

An adult male *C. flagellum* (SVL = 142.5 cm; tail length = 17.4 cm; mass = 660.0 g) fitted with a Holohil Ltd. SI-2 temperature sensor transmitter was radiotracked from 13 July 2008 to 13 June 2009, on Indio Mountains Research Station (IMRS), Hudspeth Co., Texas, USA (30.776953°N, 105.016182°W, WGS 84; 1236 m elev.). The landscape at IMRS consists of rocky slopes at higher elevations formed primarily by conglomerate and sandstone, and at lower elevations by sloping alluvial fans and flats partitioned by arroyos, with typical Chihuahuan Desert scrub covering the surface. This individual was monitored on average 6 d per month and at different times during daylight hours. We physically monitored the snake 60 times (31 times during the inactive [winter] season and 29 times during the active season [warm months]), with the following data recorded: date, time, habitat, microhabitat, facing slope, body temperature (T_b), substrate and air temperature, snake position and behavior (when visible), and distance traveled from the previous reported location. At the end of the tracking period, we estimated the snake's home range based on a minimum convex polygon (MCP) using Hawth's Analysis Tools for ArcGIS (Beyer 2004. http://www.spatialecology.com/htools); daily movement was estimated by dividing the snake's total traveled distance (m) by the total number of days that it was radiotracked (Beaupre 1995. Herpetologica 51:45–56). The home range of this snake was estimated to be 192.5 ha. The total distance traveled during the active season (March–October) was 12,105 m for 168 days, and the average daily movement was 71.6 m. However, the longest distance recorded from one day to the next was 1400 m. May, June, July, and August showed the largest monthly average movement (143.5, 164.2, 123.3, and 122.9 m, respectively). Normally, the snake was found within alluvial slope habitat (21 observations of 29 [73%]), and usually inside rodent burrows (20 observations of 29 [69%]). For 27 (93%) of the 29 observations, burrows contained vegetation on the surface, represented primarily by shrubs and grasses. In general, the surface of microhabitats had composition means of 48% vegetation, 22% gravel, and 15% plant litter. Mean T_b during the active season was 28.1°C (N = 29) and ranged from 16 to 37°C. The highest monthly T_b values were observed in June and July (33.0 and 34.1°C, respectively). The snake overwintered for 150 days (from 26 October 2008 to 4 April 2009) inside a rodent burrow, on a northwestern-facing slope composed mostly of sandstone. Although it remained on the same slope for the entire cold period, movement (ca. 10 m) inside the shelter was still detected as the cold period progressed. Mean T_b during the overwintering period was 13.7°C (N = 31), ranging from 9.4 to 19.3°C, with the lowest T_b values reported in January, and the highest at the beginning and at the end of the cold period (late October and early April). Finally, on 13 June 2009, we found a few remains of the snake along with the transmitter positioned on open ground ca. 20 m from the last reported shelter (under a shrub). We found feathers along with the snake's remains; therefore, we assume it was killed by an avian predator.

More individual snakes from the IMRS population should be monitored, including those of both sexes and various reproductive conditions and with more frequent monitoring intervals, because substantial variation is known to occur among individuals of this species (Secor, *op. cit.*; Johnson et al., *op. cit.*). Nonetheless, we use the information from this individual as an initial step and motivation factor for studies involving other populations of *M. flagellum* found in different landscapes of the Chihuahuan Desert and throughout its entire geographic range.

We thank A. Gandara and L. Miranda for their assistance during monitoring period.

VICENTE MATA-SILVA (e-mail: vmata@utep.edu), **ARTURO ROCHA**, **STEVEN DILKS**, and **JERRY D. JOHNSON**, Department of Biological Sciences, University of Texas at El Paso, El Paso, Texas 79968, USA; **LARRY DAVID WILSON**, Centro Zamorano de Biodiversidad, Escuela Agrícola Panamericana Zamorano, Departamento de Francisco Morazán, Honduras.

***COLUBER FLAGELLUM* (= *MASTICOPHIS FLAGELLUM*) (Coachwhip). DIET.** *Coluber flagellum* (= *Masticophis flagellum*) is widely distributed and feeds on a variety of prey, including invertebrates, frogs, turtles, lizards, birds, and small mammals (Ernst and Ernst 2003. Snakes of the United States and Canada. Smithsonian Institution Press, Washington, D.C. 668 pp.). They are among the few snakes quick enough to catch an active whiptail lizard (*Aspidoscelis* spp.). However, to date, only three whiptail species (*A. sexlineata*, *A. tigris*, and *A. marmorata*) are documented prey for *C. flagellum* (Reams and Aucone 2001. Herpetol. Rev. 32:108; Ernst and Ernst 2003, *op. cit.*). On 4 October 2014 we collected a DOR juvenile (SVL = 33 cm; 12.5 g) *C. flagellum* 5.0 km ESE of Marfa, in Presidio Co., Texas, USA (30.29898°N, 103.96780°W; WGS84). Upon dissection the snake was found to contain two partially digested juvenile *Aspidoscelis inornata* (Little Striped Whiptail). To our knowledge this species is a novel prey item for *C. flagellum*. The snake and lizards were collected and deposited as SRSU 6649.

SEAN P. GRAHAM, Department of Biology, Geology, and Physical Sciences, Sul Ross State University, Alpine, Texas 79830, USA (e-mail: sean.graham@sulross.edu); **CRYSTAL KELEHEAR**, Smithsonian Tropical Research Institute, Apartado 0843-03092, Balboa, Ancon, Panama (e-mail: crystal.kelehear@hotmail.com).

***CORALLUS HORTULANUS* (Amazon Treeboa). DIET.** Predation on bats by snakes is relatively infrequently reported in the literature and records are scarce in Brazil (Esbérard and Vrcibradic 2007. Rev. Bras. Zool. 24:848–853). *Corallus hortulanus* is an arboreal boid with a wide geographic distribution on the

FIG. 1. An adult *Corallus hortulanus* preying on *Glossophaga soricina* (Pallas's Long-tongued Bat) in Reserva Biológica do Parazinho, Amapá, Brazil.

neotropical mainland and several continental and oceanic islands (Henderson 1997. Carib. J. Sci. 33:198–221). *Glossophaga soricina* (Pallas's Long-tongued Bat; Phyllostomidae) is a flower-visiting bat that lives in the neotropics (Volleth et al. 1999. Chromosome Res. 7:57–64). Here we report a predation event on *G. soricina* by *C. hortulanus* in the eastern Amazon.

On 29 August 2011, at 2045 h, in the Reserva Biológica do Parazinho (0.875°N, 49.9875°W; datum WGS84), a fluvial island of the Amazon River basin, municipality of Macapá, Amapá, Brazil, an adult *C. hortulanus* (SVL = 1.6 m) was observed after capturing a *G. soricina*. The *C. hortulanus* was observed on a banana tree (*Musa* sp.) near a refuge of *G. soricina* (Fig. 1). The elapsed time from constriction to complete ingestion was 47 min. This is the first record of predation on *G. soricina* by *C. hortulanus* and our observation extends the list of bat predators in Brazil.

RAFAEL C. SANTOS (e-mail: rapha_cabral@outlook.com) and **CARLOS E. COSTA-CAMPOS**, Laboratório de Herpetologia, Departamento de Ciências Biológicas e da Saúde, Universidade Federal do Amapá, Campus Marco Zero, CEP 68903-419, Macapá, AP, Brazil (e-mail: eduardocampos@unifap.br).

***CROTALUS ATROX* (Western Diamond-backed Rattlesnake). DIET / ATTEMPTED CANNIBALISM AND SCAVENGING.** *Crotalus atrox* is a well-known, large viperid that is found across much of arid southwestern North America. The diet of this species has been studied extensively (Ernst and Ernst 2003. Snakes of the United States and Canada. Smithsonian Books, Washington, DC. 668 pp.). *Crotalus atrox* is a generalist, with the bulk of its diet consisting of small mammals and to a lesser extent, lizards. Klauber (1972. Rattlesnakes: Their Habits, Life Histories, and Influence on Mankind. 2nd ed. University of California Press, Berkeley. 1533 pp.) states that *C. atrox* is known to consume other members of the genus *Crotalus*, at least in captivity; at the San Diego Zoo an adult specimen ate a *C. molossus*, and a juvenile housed in overcrowded conditions ate a conspecific. However, ophiophagy and cannibalism have never been recorded in wild *C. atrox*. Herein I report the first recorded attempted predation by a *C. atrox* on a dead conspecific in a natural setting.

At 0237 h on 1 September 2014, a large *C. atrox* was found in the process of swallowing a smaller conspecific on US Route 385 in Brewster Co., Texas, USA, south of Marathon (30.02859°N, 103.2786°W; WGS84). When first encountered, the live *C. atrox* had approximately one third of the second snake swallowed headfirst (Fig. 1). The predation attempt was watched and photographed for approximately 15 min, however the *C. atrox* regurgitated the dead one, possibly because its body was coiled over itself (Fig. 1). The regurgitated *C. atrox* was collected and preserved (EAM761). Based on the overall condition of this specimen and its location on the highway it is likely that it was hit by a vehicle and was dead before consumption began. Also of note is that the dead individual had a large, partially digested, unidentified small mammal in its gut. Whether the scent of this small mammal was present on the partially consumed *C. atrox* and initiated the feeding event is unknown. This work was conducted under Permit No. SPR-0413-054 issued by Texas Parks and Wildlife and was funded by The Exploration Fund Grant from the Explorer's Club.

FIG. 1. *Crotalus atrox* attempted predation on a dead conspecific.

EDWARD A. MYERS, Department of Biology, College of Staten Island, 2800 Victory Blvd. 6S-143, Staten Island, New York 10314, USA, and The Graduate Center – CUNY, 365 Fifth Avenue, New York, New York 10016, USA.

***CROTALUS LEPIDUS* (Rock Rattlesnake). DIET / SCAVENGING.** *Crotalus lepidus* is usually considered to be an ambush predator that feeds primarily on lizards (Beaupre 1995. Herpetologica 51:45–56; Holycross et al. 2002. J. Herpetol. 36:589–597). Herein, we provide an account of novel opportunistic scavenging behavior in wild *C. lepidus*.

On 20 September 2014 at 2140 h we observed an adult male *C. lepidus* consume a road-killed adult male *Cophosaurus texanus* (Texas Earless Lizard) on the Indio Mountains Research Station (IMRS) Hudspeth Co., Texas, USA (30.769358°N, 105.009242°W, WGS 84; 1240 m elev.). The *C. texanus* had been an apparent victim of vehicular traffic early that morning on a dirt road on IMRS. As found in the road, the snake had not yet begun consuming the lizard, but was examining the specimen through rapid tongue flicking and physically nudging the lizard with its rostrum. The snake did not seem to be disturbed by our presence. After another brief episode of investigative behavior, the snake began swallowing the road-killed lizard by the head. The lizard displayed advanced levels of rigor mortis and desiccation, thus the snake initially struggled to swallow the specimen due to the stiff and erect position of the limbs (Fig. 1). Approximately 20 min elapsed before the entirety of the lizard was consumed. To the best of our knowledge, there are no records of scavenging by *C. lepidus* in a natural setting, although it has been described in several congeners (DeVault and Krochmal 2002. Herpetologica 58:429–436). However, *C. texanus* is a known prey item of *C. lepidus* on IMRS, and trailing behavior has been observed in *C. lepidus* during some of these predation events (Mata-Silva et al. 2011. Herpetol. Rev. 42:439). Our fortuitous

FIG.1. An adult male *Crotalus lepidus* scavenging a road-killed *Cophosaurus texanus* at Indio Mountains Research Station, Hudspeth Co., Texas, USA.

observation suggests that *C. lepidus* use alternative modes of foraging in addition to an ambush approach.

Special thanks to J. Sandoval and S. Baqla for their assistance in the field.

DOMINIC DESANTIS (e-mail: dldesantis@miners.utep.edu), **VICENTE MATA-SILVA,** and **JERRY D. JOHNSON**, Department of Biological Sciences, University of Texas at El Paso, El Paso, Texas 79968, USA.

***CROTALUS OREGANUS* (Northern Pacific Rattlesnake). NON-RATTLING TAIL DISPLAY.** Rattlesnakes exhibit three main tail displays: 1) rattling, an aposematic signal directed at predators (Klauber 1972. Rattlesnakes: Their Habits, Life Histories, and Influence on Mankind. University of California Press, Berkeley. 1580 pp.); 2) caudal luring, a form of aggressive mimicry used to attract insectivorous prey (e.g., Reiserer and Schuett 2008. Biol. J. Linn. Soc. 95:81–91); and 3) non-rattling defensive displays, exhibited by some species upon tactile stimulation (Rabatsky and Waterman 2005. Herpetol. Rev. 36:236–238). We recorded three instances of adult *Crotalus oreganus* exhibiting a non-rattling tail display. This display consists of snakes slowly flagging their raised tails from side to side (Fig. 1), and does not appear to function in prey capture or defense, making it different from previous reports of non-rattling displays in rattlesnakes. We recorded this behavior in one female and two males using fixed videography (Sony SNC-RZ25N cameras) at our field site, Blue Oak Ranch Reserve, Santa Clara Co., California (37.38208°N, 121.71209°W, WGS84; 800 m elev.). Our video cameras ran over a wireless internet connection and were controlled remotely by field assistants who watched their video feeds in real time at the field site. Their field of view was typically no more than 1.0–1.5 m. Our site's habitat is characterized by mixed oak woodland interspersed by grassland. Video of the tail displays can be viewed on our lab YouTube channel (https://youtu.be/__AXL4FYqIA).

The female (SVL = 79.5 cm) was recorded on 12 June 2011. We had implanted a radio-transmitter in her on 29 May 2011. At the time of the tail display, we considered her not recovered from surgery because she had not moved from the location where we released her and because she exhibited behaviors consistent with recovery (periodically moving in and out of one refuge and using a loosely coiled body position). She had emerged from her rocky burrow refuge at 1514 h that day and was approximately 30 cm from its entrance when the behavior occurred. In addition, she was fully exposed and no other animals were present on camera. At 1523 h, she lifted her tail above her body and proceeded to move it from side to side a total of 9 times over the course of 124 sec. Eighty-six seconds after ceasing this tail display, she moved her head toward her burrow (thus becoming partially elongated) and rested in that position for 33 sec. She retreated to the burrow at 1528 h. She remained at the site, presumably recovering from surgery, until 25 June 2011.

We recorded a tail display in one male (SVL = 71.0 cm) on 9 June 2012. We implanted him with a radio-transmitter on 28 April 2012 and considered him recovered from surgery at the time of his display. This snake was within thick vegetation (mainly Bull Thistle, *Cirsium vulgare*) when the behavior occurred, and he also appeared alone as no other animals were present on camera. He arrived to the site at 1306 h and started the tail display at 1310 h by slowly moving his raised tail to one side (a behavior that lasted 6 sec). He moved his tail to the other side of his body 57 sec later (a movement that lasted 7 sec). He then exhibited two tail side sweeps 242 sec later (the first lasted 6 sec, the second lasted 11 sec). Forty-four seconds after ceasing the tail display, he probed the area for 74 sec by moving his head around and tongue-flicking. He abandoned the site at 1318 h, but only moved approximately 30 cm where he coiled in a new position. He remained at that site for 1–2 days thereafter.

Our recording of the other male that exhibited a tail display is the most striking. This male (SVL = 101.0 cm) was implanted with a radio-transmitter on 29 May 2011 and was considered recovered from surgery. He appeared to exhibit the tail display in response to the presence of another adult male (SVL = 97.0 cm). Their interaction occurred on 2 July 2011, although they had been sharing the same burrow since 1700 h on 1 July 2011. The snake that exhibited the display (called Snake P) emerged from their shared burrow at 1303 h while the other snake (called Snake M), emerged at 1304 h. Snake P quickly assumed an S-shaped body posture approximately 60 cm from the burrow next to a fallen branch, while Snake M continued to slowly emerge from the burrow. The majority of Snake P's body was not within the camera frame when he began the tail display, but we were able to see his tail moving at 1307 h and 54 sec and a field assistant then used the pan/tilt/zoom function of the camera to center his body in the frame. At this time, Snake M remained elongated out of the burrow with his head on top of the body of Snake P. Snake P moved his raised tail from one side of his body to the other a total of 9 times over the course of 14 sec (Fig. 1), and Snake M moved his head over Snake P while tongue flicking. Snake P also tongue flicked during this interaction. Snake M retracted his head from off the body of Snake P, but remained close by. An adult California Ground Squirrel (*Otospermophilus beecheyi*) approached the snakes at 1311 h and immediately ran away (on camera < 4 sec). Snake P exhibited another bout of tail waving at 1313 h, moving his tail from side to side a total of 6 times over the course of 13 sec. At 1313 h and 34 sec, we observed Snake M moving his upper body back toward the burrow while tongue flicking. Snake M immediately began to retreat into the burrow, but then stopped abruptly at 1313 h and 50 sec. Snake M started movement again at 1314 h and 59 sec, but changed directions and moved to the left of the burrow and under the fallen oak branch. Snake P quickly fled the site at 1318 h. Snake P kept his tail raised above his body the entire time after first exhibiting the tail display and before leaving the site. We did not immediately track Snake P after this interaction so we lack data on the distance he moved after exhibiting the tail display. However, we found him with a large food bulge at 1630 h, and we deducted that he had consumed

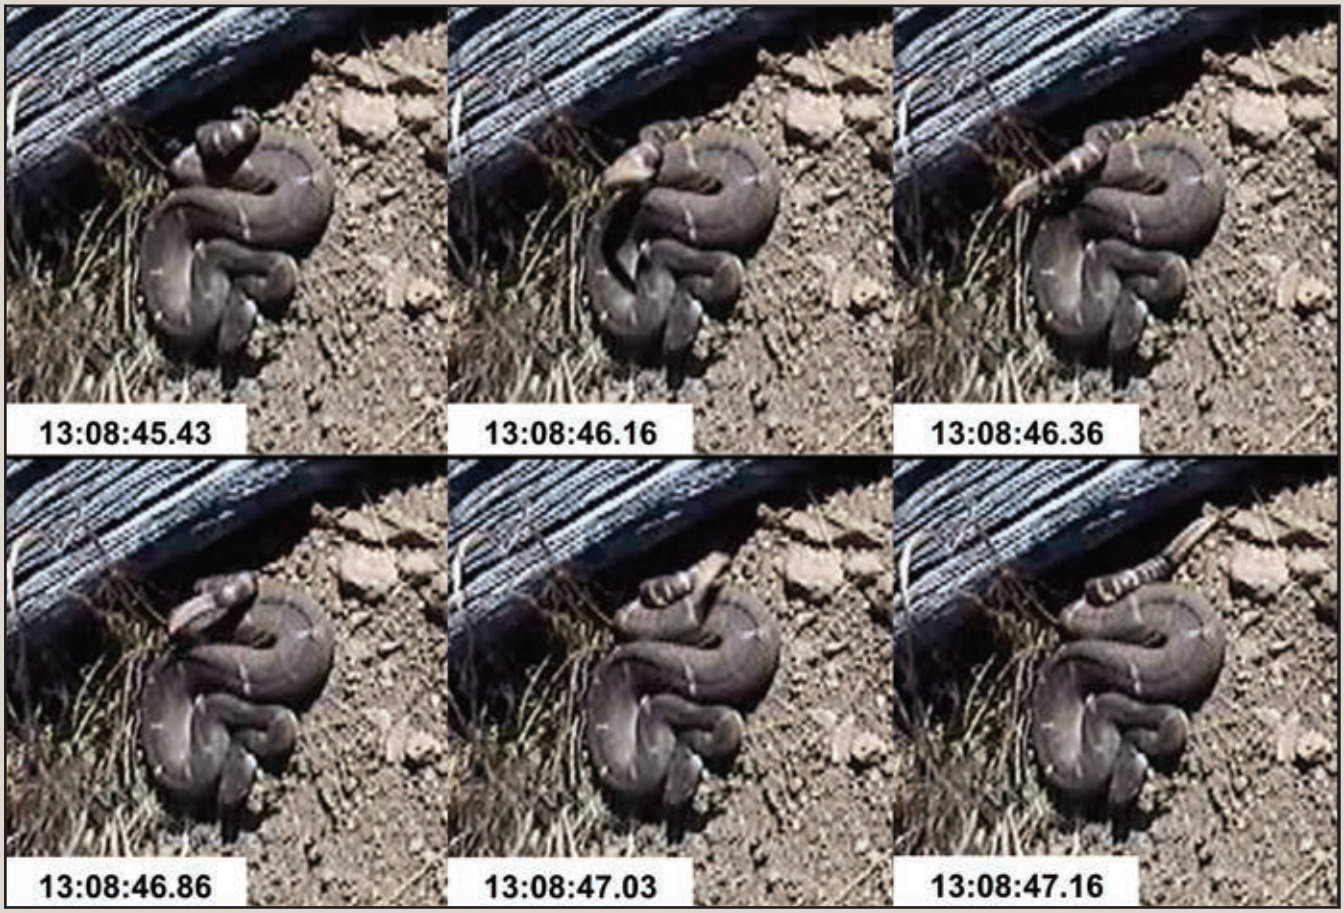

FIG. 1. Time-series of an adult male *Crotalus oreganus* exhibiting two flags from a non-rattling tail display bout. Time flows from left to right, top to bottom.

an adult squirrel because no other prey items at our site are comparable in body size.

Collecting precise descriptions of the contextual stimuli that elicit snake tail displays is necessary to better understand their function. The three instances we report above have a few commonalities. First, all snakes were in a loosely coiled body position. Second, the snakes exhibited the display intermittently over several minutes (approximately 2–6 min), then left their sites almost immediately after. Finally, the cloaca of the snakes appeared swollen when they were displaying, which could indicate that fluids were released from the cloaca and could function in communication. It is unlikely this tail display functions to attract prey because none of the rattlesnakes were in hunting body positions (ambush coil) when they exhibited the behavior. Many snake tail displays have an antipredator function (Greene 1973. J. Herpetol. 7:143–161), but no predatory threat was visible on camera (although predators could have been close by) when our rattlesnakes displayed. Furthermore, when threatened, rattlesnakes typically rely on crypsis before mounting behavioral defenses and many studies have shown that tactile stimulation or intense harassment are needed to induce behavioral defenses in exposed vipers (Glaudas et al. 2005. Copeia 2005:196–200; Maritz 2012. Afr. Zool. 47:270–274). Given that our snakes were not visually disturbed prior to waving their tails, it is unlikely that this display functions in defense against predators.

The tail displays we observed are likely functional considering the deliberate, prolonged movements and the attention they could draw to otherwise cryptic snakes. Other pitvipers use tail displays during conspecific interactions. Tail writhing is displayed by defeated males after male-male combat in *Agkistrodon contortrix* (Schuett 1997. Anim. Behav. 54:213–224). Female *Crotalus molossus* that are disinterested in courting males have been observed exhibiting tail displays similar to what we recorded (E. Taylor, pers. comm.). Non-defensive tail displays in *C. oreganus* may thus be used to communicate with conspecifics, although this idea is speculative given our small sample size. We only captured one recording of two male rattlesnakes interacting when the tail display occurred, although conspecifics could have been close by but not visible in our other recordings due to our restricted field of view. The two males we recorded interacting did not behave aggressively toward each other. In addition, we did not film rattlesnakes during breeding seasons so we cannot associate these displays with mating behaviors. More observations are needed to formulate testable hypotheses concerning this behavior.

These observations were made possible in part by funding from the National Science Foundation (DBI-0951010 to RWC) and assistance from Michael Hamilton of the Blue Oak Ranch Reserve along with many hard-working undergraduate field assistants.

BREANNA J. PUTMAN (e-mail: putman.bree@gmail.com) and **RULON W. CLARK,** Department of Biology, San Diego State University, 5500 Campanile Drive, San Diego, California 92182-4614, USA.

***CROTALUS SCUTULATUS* (Mohave Rattlesnake). MAXIMUM SIZE.** Here, we report the longest accurately measured *Crotalus scutulatus*. The adult male *C. scutulatus* was captured mid-morning on 16 September 2014, in Eloy, Pinal Co., Arizona, USA (32.780383°N, 111.613144°W; WGS84). The snake was coaxed into a clear plastic tube and triplicate measurements were taken with the anterior part of the snake in the tube and the posterior part straightened out by hand along a measuring tape (Fig. 1). Mean measurements (± Standard Deviation) were: SVL = 1136.7 (± 5.7) mm, tail length = 90.3 (± 2.4) mm. Therefore the total length of the specimen (excluding the rattle) is 1236 mm.

Crotalus scutulatus measuring over 1000 mm are not common, and the maximum verified total length (excluding rattle) to date is 1135 mm (Cardwell 2015. Rattlesnakes of Arizona. *In press*. ECO Publishing, Rodeo, New Mexico). While there have been a few previous reports of animals over 1200 mm long, none of these reports have been authenticated (Cardwell 2015, *op. cit.*). A male specimen of length 1231 mm reported by Klauber remains unconfirmed as the datasheet has not been located (Cardwell 2015, *op. cit.*). Tennant (1984. The Snakes of Texas. Texas Monthly Press, Austin, Texas. 561 pp.) initially reported a male measuring 1373 mm from Brewster Co., Texas, USA, but later questioned this due to possible misidentification (Cardwell 2015, *op. cit.*). Finally, Lowe et al. (1986. The Venomous Reptiles of Arizona. Arizona Game and Fish Dept., Phoenix. 115 pp.) described the maximum length of *C. scutulatus* as 1321 mm, but the source of this is untraceable and is suspected to be a digit-switching error while reporting Klauber's data (Cardwell 2015, *op. cit.*). Our specimen, with a total length of 1236 mm is consequently the longest *C. scutulatus* that has been accurately measured and reported. The specimen is now in the live collection of the Chiricahua Desert Museum, Rodeo, New Mexico.

We thank Michael D. Cardwell for access to his book chapter and additional useful information. Research partly funded by Leverhulme Trust grant RPG-2013-315 to WW.

***CROTALUS WILLARDI* (Ridge-nosed Rattlesnake). REPRODUCTION / MALE COMBAT.** In certain lineages of snakes, males compete for priority-of-access to females as mates by way of direct fighting, often called male combat (Carpenter et al. 1976. Copeia 1976:764–780; Shine 1978. Oecologia 33:269–277; Schuett 1997. Anim. Behav. 54:213–224). In rattlesnakes and numerous other pitviper species, male combat involves rearing, vertical posturing, entwining, constriction, and thrashing (Schuett, *op. cit.*; Schuett et al. 2001. Acta Ethol. 4:31–49). Here, we report on male combat in *Crotalus willardi* from a population in Arizona. To the best of our knowledge, male combat has not been described in *C. willardi* in the wild or in captivity (Shine 1994. Copeia 1994:526–546; Schuett et al., *op. cit.*; Ernst and Ernst 2012. Venomous Reptiles of the United States, Canada, and Northern Mexico. vol. 2, Johns Hopkins University Press, Baltimore, Maryland. 399 pp.).

On 8 August 2008, at 0955 h, on a small hillside (elev. 1646 m) in the Patagonia Mountains (Arizona, Santa Cruz Co., USA, 31.416°N, 110.733°W; datum Conus 27; highest elev. 2201 m), one of us (BPO) observed two adult *C. willardi* engaged in male combat (Fig. 1A). The snakes were similar in size, but were easily distinguishable by their body color (dark brown vs. light brown) and number of rattle segments (Fig. 1B). Neither individual was captured; thus, sex was not directly confirmed. Combat proceeded in typical stereotypic fashion, with both individuals raising their bodies above the substrate and attempting to attain a superior position (Schuett et al., *op. cit.*). Other acts included swaying, entwining, and falling. After several minutes they would rest then reinitiate combat. Both individuals used a rock and low-lying branches for stability during vertical postures of combat. At 1011 h, observations of the snakes were halted for 20 min; when observation resumed, the light male was found about 7 m up slope along a rock cut where he

PHOTOS BY BRENDAN P. O'CONNOR

FIG. 1. Male combat in *Crotalus willardi* in the Patagonia Mountains, Arizona. A) Males in vertical postures. B) Males entwined, constricting, and one is exhibiting a superior position.

was stretched out and in a relaxed position. The dark male was not located after searching for 10 min. Actual combat was observed for approx. 16 min, and the total duration of the observation was 56 min. Although a female *C. willardi* was not located in the immediate vicinity, this does not preclude a female's presence owing to this species' extremely cryptic behavior. The combat observation we document occurred during the time of summer that is commonly reported as the mating season for this species in the northern region of its range (Holycross and Goldberg 2001. Copeia 2001:473–481; Ernst and Ernst 2012, *op. cit.*).

We thank Ryan Sawby for assistance in preparing the figure.

***DRYMARCHON MELANURUS EREBENNUS* (Texas Indigo Snake). DIET / SCAVENGING.** *Drymarchon melanurus erebennus* is a state (Texas) protected species with a wide distribution including all of the South Texas Plains and portions of the southern Edwards Plateau eco-regions. *Drymarchon m. erebennus* is an opportunistic generalist that feeds on a broad spectrum of vertebrates including rodents, birds, frogs, small turtles, lizards, and serpents. Smith and Antonio (2007. Herpetol. Rev. 38:88) report carrion feeding by the allopatric *D. couperi* (Eastern Indigo Snake) on a disarticulated shark head. Herein we report, to the best of our knowledge, the first observation of *D. m. erebennus* eating carrion in the wild.

On 27 March 2007, an adult *D. m. erebennus* was observed in the process of swallowing a dead *Crotalus atrox* (Western Diamond-backed Rattlesnake) (Fig. 1). The *C. atrox* had been killed two days earlier and draped over a barbed-wire fence. The carcass was bloated and exhibited an advanced state of decomposition. The carcass hung from a barb, causing the *D. m. erebennus* to rise from the ground during the early stages of consumption. Thereafter we removed the carcass from the fence and observed as consumption proceeded over the next two hours. The observation occurred approximately 4 km W of Yancey, Medina Co., Texas, USA (29.14894°N, 99.18679°W, datum WGS84; elev. 217 m). A photo voucher (TNHC 91021) was deposited in the Texas Natural History Collection at the University of Texas.

***DRYOCALAMUS SUBANNULATUS* (Malayan Bridle Snake). BEHAVIOR.** In Southeast Asia, two genera of climbing snakes, *Dryocalamus* and *Lycodon*, are morphological Batesian mimics of the highly venomous kraits in the genus *Bungarus*. *Bungarus* snakes exhibit a dark brown or black background with bands of white, yellow, or tan, which together provide an appearance of alternating dark and light bands. *Dryocalamus* and *Lycodon* snakes, although differing from *Bungarus* species in other morphological characters, mimic this alternating dark and light color pattern. In Thailand, the color pattern of *Dryocalamus subannulatus* is thought to mimic that of *Bungarus candidus*, and the ranges of these two species overlap by at least 50%. Hospitals in Thailand report (Viravan et al. 1992. Trans. Roy. Soc. Trop. Med. Hyg. 86:100–106) that *Dryocalamus* snakes are brought in by snakebite victims believing they have been bitten by a *Bungarus* species.

At 2122 h on 31 July 2014, we observed a *D. subannulatus* in a dry evergreen forest at Sakaerat Environmental Research Station in Nakhon Ratchasima Province, Thailand (14.5060°N, 101.9276°W, WGS84; 435 m elev.). The snake was stretched horizontally (Fig. 1A), 22 cm above the ground, across the trunk of

PHOTOS BY N. KARRAKER

FIG. 1. *Dryocalamus subannulatus* when (A) first observed, and (B) mimicking head-hiding behavior of *Bungarus* species.

PHOTOS BY A. DEVAN-SONG

FIG. 2. *Bungarus candidus* exhibiting head-hiding behavior at Sakaerat Environmental Research Station, Thailand in 2012.

a *Hopea ferrea* tree (52 cm diam at 1.0 m above the ground). As we watched, the snake initially doubled its body back across the trunk and began probing crevices, seemingly searching for cover. Within one minute, and without any physical disturbance by us, the snake began coiling its body on the trunk and tucked its head beneath its body (Fig. 1B), in a behavior similar to that of *B. candidus* (Fig. 2), *B. fasciatus* (Karsen et al. 1998. Hong Kong Amphibians and Reptiles. Provisional Urban Council, Hong Kong. 134 pp.), and *B. multicinctus* (Glass 1946. Copeia 1946:249–252). As we attempted capture, the snake lunged to the side and attempted flight, a behavior similar to the defensive side strike we have observed in *B. candidus* and *B. fasciatus*. We captured the male *D. subannulatus*, at which time it was measured (SVL = 49.9 cm; total length = 69.0 cm) and weighed (17.7 g). The snake was released where it was found.

Some other colubrids exhibit head-hiding behavior, but this behavior has largely been induced in response to a "predatory attack," often involving tapping on the head, by a researcher (e.g., Langkilde et al. 2004. Ethology 110:937–947). We have observed *Bungarus* spp. engage in head-hiding behavior on numerous occasions with no interference from us other than illumination by a headlamp, as was the case with the *D. subannulatus*. Our observations suggest that *D. subannulatus* may be both a morphological and behavioral mimic of *B. candidus*.

***ELAPHE QUADRIVIRGATA* (Japanese Four-lined Ratsnake). DIET.** *Elaphe quadrivirgata* is endemic to the main islands of Japan, and is known as a general predator of arthropods, amphibians, reptiles, birds, and mammals (Mori and Moriguchi 1988. Snake 20:98–113). However, there are no reports of predation on annelid worms. During fieldwork at Ito campus, Kyushu University, Fukuoka, Japan (33.5983°N, 130.2145°E; datum Analysis by GSIMaps) at 1527 h on 16 June 2014, we recovered an earthworm from an *E. quadrivirgata* (female; SVL = 86.5 cm) by forced regurgitation (Fig. 1); no other stomach contents were obtained from the snake. This is the first report of predation on earthworms by *E. quadrivirgata* in the wild. The earthworm was dissected and

FIG. 1. *Metaphire* sp. recovered from an *Elaphe quadrivirgata* at Ito campus, Kyushu University, Fukuoka, Japan.

identified as *Metaphire* sp. (Megascolecidae). The earthworm specimen was deposited in the Zoological collection of Kyoto University (KUZ Z704).

***GYALOPION QUADRANGULARE* (Thornscrub Hook-nosed Snake). DEFENSIVE BEHAVIOR / CLOACAL POPPING.** At 2245 h on 16 July 2014, a *Gyalopion quadrangulare* was encountered crossing a road west of Nogales, Santa Cruz Co., Arizona, USA, by RDB. When picked up for examination, the snake writhed, thrashed, and issued a series of 4–6 cloacal pops. The snake repeated this display the following morning when removed from its container. At 2011 h on 20 September 2014, another *G. quadrangulare* was found crossing a road by DDK. When picked up, the snake thrashed wildly, emitted a sharp sneeze or spit, and cloacal popped for 2–3 min, even after being placed in a collecting bag. Cloacal popping is a defensive behavior where contraction of the cloacal muscles forces air over the anal plates producing controlled flatulence and is currently known to be employed by only three species of North American snakes: *Micrurus fulvius* (Harlequin Coralsnake), *Micruroides euryxanthus* (Sonoran Coralsnake), and *Gyalopion canum* (Chihuahuan Hook-nosed Snake; Young et al. 1999. J. Herpetol. 33:557–566).

***HELICOPS LEOPARDINUS* (Watersnake). DIET.** *Helicops leopardinus* is a Neotropical aquatic snake, frequently found in flooded areas associated with floating vegetation (Hoogmoed 1993. *In* P. E. Ouboter [ed.], Freshwater Ecosystems of Suriname, pp. 199–213. Kluwer Academic Publishers, Amsterdam, Netherlands). It is generally nocturnal and feeds primarily on fish, tadpoles, and adult frogs (Martins and Oliveira 1998. Herpetol. Nat. Hist. 6:78–150; Ávila et al 2006. J. Herpetol. 40:274–279). Here, we describe a diurnal predation event by *Helicops leopardinus* on *Synbranchus marmoratus* (Pisces: Synbranchiformes).

On 15 October 2013, at 1128 h, while conducting a herpetological survey in the Reserva Extrativista Beija Flor Brilho de Fogo (0.804464°N, 52.212533°W, WGS84; 123.5 m elev), municipality of Pedra Branca do Amapari, Amapá state, Brazil, we discovered a female *H. leopardinus* (SVL = 590 mm, tail length = 138 mm) that was preying on a Swamp Eel, *S. marmoratus* (total length = 194 mm), in the water. When found, the *H. leopardinus* was biting the opercula area of the eel, but soon began ingesting the eel headfirst. After 14 min, the snake was captured, causing it to release the eel. Both specimens have been deposited in the Coleção Didática do Laboratório de Zoologia, Universidade Federal do Amapá, Amapá, Brazil. This research was authorized by permit number 41443-1 ICMBio.

***HELICOPS LEOPARDINUS* (Watersnake). DIET.** *Helicops leopardinus* (Dipsadidae) is an aquatic and nocturnal species, frequently found in flooded areas associated with floating vegetation (Hoogmoed 1993. *In* P. E. Ouboter [ed.], Freshwater Ecosystems of Suriname, pp. 199–213. Kluwer Academic Publishers, Amsterdam, Netherlands). It is a generalist in terms of diet, consuming fishes, tadpoles, and occasionally adult amphibians (Ávila et al 2006. J. Herpetol. 40:274–279). Here we describe a field observation of predation on *Leptodactylus macrostenum* (Anura: Leptodactylidae) by *H. leopardinus* in Eastern Amazonia.

On 27 June 2014, at 1819 h, in the floodplain at Área de Proteção Ambiental do Curiaú (0.153444°N, 51.014972°W; datum WGS84), municipality of Macapá, Amapá, Brazil, we encountered an adult female *H. leopardinus* with an adult male *L. macrosternum* that it had seized and partially ingested, hind limbs first (Fig. 1). For approximately 27 min we observed the snake attempting to consume the frog. During this predation event, the frog emitted a sequence of distress calls. Upon capture, the *H. leopardinus* (SVL = 467 mm; Tail length = 110 mm; 98 g) regurgitated the *L. macrosternum* (SVL = 72.4 mm; 36 g). The frog and the snake were collected and deposited at the Herpetological Collection of the Universidade Federal do Amapá (CECCAMPOS 00864, 00865, respectively; ICMBio collecting permit number 41586-1). This report is the first record of *L. macrosternum* as prey of *H. leopardinus*, suggesting opportunistic feeding on frogs at breeding sites.

Fig. 1. *Helicops leopardinus* feeding on a *Leptodactylus macrosternum* in Eastern Amazonia, Brazil.

MELO FURTADO**, and **JÉSSICA CANELA VAZ**, Laboratório de Herpetologia, Departamento de Ciências Biológicas e da Saúde, Universidade Federal do Amapá, Campus Marco Zero do Equador, 68.903-419, Macapá, AP, Brazil.

***HYPSIGLENA JANI* (Texas Nightsnake). DIET.** *Hypsiglena jani* is a small dipsadine that is widespread within the Chihuahuan Desert of North America. The diet of nightsnakes has been well studied (Rodríguez-Robles et al. 1999. Copeia 1999:93–100) and consists primarily of phrynosomatid lizards and squamate eggs. Although species of *Phrynosoma* are widely sympatric with species of *Hypsiglena,* these lizards have only been recorded as a prey item once before and never for *H. jani* (*H. chlorophaea;* O'Connor et al. 2010. Northwest. Nat. 91:79–81).

While road-cruising in Eddy Co., New Mexico, USA, we observed an adult *H. jani* attempting to consume a *P. cornutum* (Fig. 1). The specimen was discovered the night of 27 August 2013 on Queens Highway west of Carlsbad (32.42759°N, 104.54283°W; WGS84). When first observed, the *H. jani* was in the process of chewing on the neck of the *P. cornutum*, likely facilitating envenomation of the lizard. The snake made multiple attempts to swallow the lizard; however, given the small size of the snake and the large size of the cranial horns possessed by the *P. cornutum,* actual consumption would have been unlikely. Both snake and lizard were collected and preserved (*H. jani*, EAM199; *P. cornutum,* EAM198); the *Phrynosoma* died before morning presumably as a result of its envenomation. This work was conducted under Permit No. 3559 issued by the New Mexico Department of Game & Fish to EAM.

Fig. 1. *Hypsiglena jani* biting the neck of *Phrynosoma cornutum* west of Carlsbad, New Mexico, USA.

EDWARD A. MYERS, Department of Biology, College of Staten Island, 2800 Victory Blvd. 6S-143, Staten Island, New York 10314, USA, and The Graduate Center – CUNY, 365 Fifth Avenue, New York, New York 10016, USA (e-mail: emyers@gc.cuny.edu); **MARIANO SOLEY-GUARDIA**, Department of Biology, The City College of New York, 160 Convent Ave., New York, New York 10031, USA, and The Graduate Center – CUNY, 365 Fifth Avenue, New York, New York 10016, USA (e-mail: msoley@gc.cuny.edu).

***MICRURUS DISTANS DISTANS* (West Mexican Coralsnake). DIET.** Endemic to western Mexico, *Micrurus distans* occurs at low to moderate elevations from southwestern Chihuahua and southern Sonora, southward on the Pacific drainage through Sinaloa, Nayarit, Jalisco, Colima, and Michoacán to Guerrero (Ernst and Ernst 2011. Venomous Reptiles of the United States, Canada, and Northern Mexico: Volume 1. Johns Hopkins University Press, Baltimore, Maryland. 392 pp.). The diet of this terrestrial species is comprised predominantly of snakes (Roze 1996. Coral Snake of the Americas: Biology, Identification, and Venoms. Krieger Publishing Co., Malabar, Florida. 340 pp.). Herein, we report the first documented instance of predation on *Drymarchon melanurus* (Central American Indigo Snake) by *M. d. distans*.

At 0940 h on 25 August 2014, we found an adult female *M. d. distans* (SVL = 770 mm; UCM AC-184; Fig. 1A) 1 km E of Alamos, Sonora, Mexico (27.02365°N, 108.92466°W; WGS 84). Later the same day, the snake disgorged a hatchling-sized *D. melanurus* (SVL ca. 457 mm; UCM AC-185) that had been swallowed headfirst (Fig. 1B). To our knowledge, this is the first report of *D. melanurus* in the diet of *M. d. distans*.

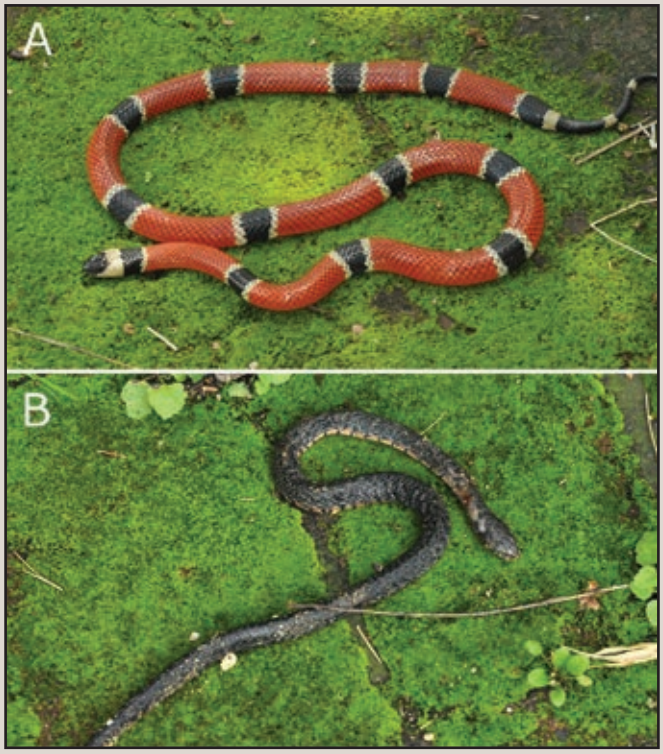

Fig. 1. A) Adult *Micrurus distans distans* from Alamos, Sonora, Mexico, that consumed a juvenile *Drymarchon melanurus*. B) Juvenile *D. melanurus* regurgitated by the *M. d. distans*.

STEVENSON**, The Orianne Society, 414 Club Drive, Hinesville, Georgia 31313, USA (e-mail: dstevenson@oriannesociety.org).

***MICRURUS MIPARTITUS* (Red-tailed Coral Snake, Coral Rabo de Ají). DIET / OPHIOPHAGY.** Coral snakes are predators of elongate vertebrates such as snakes, fishes, caecilians, lizards, and amphisbaenians (Savage 2002. The Amphibians and Reptiles of Costa Rica: A Herpetofauna between Two Continents, between Two Seas. University of Chicago Press, Chicago, Illinois. 704 pp.). It is presumed that *Micrurus mipartitus* preys on other snakes in its natural environment (Guyer and Donnelly 2004. Amphibians and Reptiles of La Selva, Costa Rica, and the Caribbean Slope. University of California Press, Berkeley. 367 pp.), with data on consumption of *Atractus* snakes in captivity (Ayerbe et al. 1990. Nov. Colomb. 2:30–41). It has also been reported that *M. mipartitus* feeds upon on amphibians such as *Caecilia thompsoni* (Hernando-Bernal and Milena-Palma 2011. Herpetol. Rev. 42:617) and *Gymnopis multiplicata* (Saporito 2007. Herpetol. Rev. 38:199). Herein, we document the snake *Atractus manizalesensis* as prey of *M. mipartitus* in a natural environment.

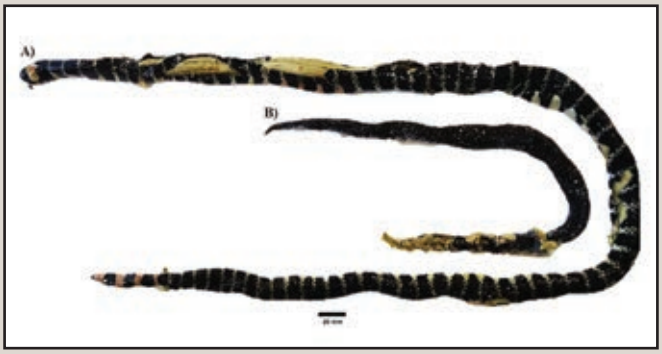

Fig. 1. Adult *Micrurus mipartitus* (A) with stomach contents, an adult female *Atractus manizalesensis* (B).

On 30 July 2013, we found a dead adult male *M. mipartitus* (MHN-UC 255; SVL = 753.7 mm; total length = 758 mm) on an unpaved road at Vereda Floresta, municipality of Villamaría, Department of Caldas, Colombia (5.0205138°N, 75.5225305°W, WGS84; 1790 m elev.). Its stomach contained an adult female *A. manizalesensis* (Fig. 1; MHN-UC 256; total length = 323 mm), partially digested in the anterior region and ingested headfirst; it represented ca. 42.6% of the predator's total length. The specimens are housed in Museo de Historia Natural de la Universidad de Caldas (MHN-UC), Manizales, Colombia.

We thank J. A. Rojas for help with prey identification and P. D. A. Gutiérrez-Cárdenas for valuable comments on the manuscript.

***NERODIA SIPEDON* (Northern Watersnake). SCAVENGERS.** Some *Limenitis* species of butterfly are known to feed on carrion (Downes 1973. J. Lepidopterists Soc. 27:89–99), and in the past lepidopterists have used decomposing snakes hung from trees to attract uncommon woodland species (Clark 1932. The Butterflies of the District of Columbia and Vicinity. U.S. Natl. Mus., Bull. 157, 337 pp.). However, here I present the first known observation of *Limenitis* (i.e., *Limenitis arthemis astyanax*; Red-Spotted Purple Butterfly) feeding on *Nerodia sipedon*. On 28 July 2013, a *L. a. astyanax* was observed scavenging on a roadkilled subadult *N. sipedon* in Mahwah City, Bergen Co., New Jersey, USA. The butterfly was observed feeding for approximately 90 min on areas of exposed muscle tissue where skin had been torn away by vehicles. Adult Lepidoptera can only imbibe solutions with particles small

FIG. 1. *Nerodia sipedon* scavenged by *Limenitis arthemis astyanax*, Mahwah City, New Jersey, USA.

enough to pass through the proboscis and exposed muscle tissue provides both minerals and salts of appropriate size. The snake was scavenged for two consecutive days (90 min/day), either by the same returning individual butterfly or by multiple individuals.

***PANTHEROPHIS SPILOIDES* (Gray Ratsnake), *AGKISTRODON PISCIVORUS* (Cottonmouth), *COLUBER CONSTRICTOR* (North American Racer), *THAMNOPHIS PROXIMUS* (Western Ribbonsnake). AGGREGATION BEHAVIOR.** Observations of multi-species aggregations of snakes are rare (Gregory 2004. Herpetologica 60:178–186) and this behavior remains poorly understood. On 8 November 2013 at 0900 h on a clear, cool, sunny morning (12.8°C) at the Turtle Cove Environmental Research Station of Southeastern Louisiana University on Pass Manchac in southeastern Louisiana, USA (30.294034°N, 90.335046°W; WGS84), a group of students flipped several overlapping pieces of 2´ x 12´ sheets of tin and found six snakes of four species: two *Pantherophis spiloides*, two *Coluber constrictor*, one *Agkistrodon piscivorus*, and one *Thamnophis proximus*. One *P. spiloides* and one *C. constrictor* were entwined and the other *C. constrictor* and *P. spiloides* were in elongate coils less than an inch apart from each other. The *A. piscivorus* was coiled adjacent to the latter four snakes and the *T. proximus* was separated from the others by ~ 1 m.

Multi-species aggregations are rare, as is speculation on why they occur (Gregory et al. 1987. *In* Seigel et al. [eds.], Snakes: Ecology and Evolutionary Biology, pp. 366–395. MacMillan Publ. Co., New York; Gregory 2004, *op. cit.*). Heat retention and water loss prevention have been two proposed explanations. In this case we speculate the snakes shared the cover for thermal reasons. We do not know if the snakes sheltered all night there (all the species mostly exhibit diurnal activity), but it would seem plausible that they used the warm tin as shelter overnight and for rapid warming with the morning insolation. Others have noted that individual snakes in multi-species aggregations are never "strongly dissimilar in size" (Gregory 2004, *op. cit.*). However, of the six individuals, the *A. piscivorus* and *T. proximus* were distinctly smaller than the others. The Cottonmouth was a juvenile still in possession of the characteristic lemon-colored tail.

RONALD ADAMS (e-mail: ronald.adams@selu.edu), and **BRIAN I. CROTHER**, Department of Biological Sciences, Southeastern Louisiana University, Hammond, Louisiana 70402, USA.

***PITUOPHIS CATENIFER AFFINIS* (Sonoran Gophersnake). DIET.** *Pituophis catenifer affinis* is a common species throughout central New Mexico that has been reported to feed primarily on mammals. However, it will opportunistically feed on a variety of prey items including birds (Ernst and Ernst 2003. Snakes of the United States and Canada. Smithsonian Books, Washington, D.C. 668 pp.) and bird eggs (Degenhardt et al. 1996. The Amphibians and Reptiles of New Mexico. University of New Mexico Press, Albuquerque, New Mexico. 431 pp.), although eggs might be consumed secondarily (Fitch 1999. A Kansas Snake Community: Composition and Changes over 50 years. Krieger Publishing Co., Malabar, Florida. 165 pp.). At ca. 1030 h on 27 July 2010, while conducting *Coccyzus americanus occidentalis* (Western Yellow-billed Cuckoo) telemetry studies (Sechrist et al. 2012. Western Birds 43:2–11), we recorded a *P. c. affinis* predating a *C. a. occidentalis* nest containing three eggs near The Narrows, Sierra Co., New Mexico, USA (33.2219°N, 107.1048°W; datum WGS84). The nest was located 6.2 m above the ground, nestled in a fork of a live 10.6-m tall *Salix gooddingii* (Gooding's Willow). A remote camera captured a nine-second video of the predation event, although it is likely the event lasted longer. Nest predation was partial; two of three eggs were missing when the camera was removed. The nest was successful in producing one fledgling. To our knowledge, this is the first report of *C. a. occidentalis* nest predation by *P. c. affinis*. We thank the Albuquerque Area Office of the Bureau of Reclamation for funding.

***REGINA SEPTEMVITTATA* (Queensnake). DEFENSIVE BEHAVIOR / DEATH-FEIGNING.** Death-feigning behavior or thanatosis, a defensive behavior against predation characterized by lack of movement, has been documented in a number of snake species (Gehlbach 1970. Herpetologica 26:24–34). Here we report an observation of death-feigning behavior in juvenile *Regina septemvittata*. At 1400 h on 27 June 2014, two juvenile *R. septemvittata* were captured in Little Hickman Creek in Jessamine Co., Kentucky, USA (37.7715°N, 84.5710°W; WGS84), as part of an ongoing capture-mark-recapture project. Upon handling, the snakes exhibited death-feigning behavior, remaining motionless with the ventral parts of their bodies facing upward (Fig. 1). The behaviors lasted for approximately 10 min before the snakes became active.

FIG. 1. Death-feigning in *Regina septemvittata* from Jessamine Co., Kentucky, USA.

Photographs and video were taken of the event and the snakes were subsequently released at capture locations. Prior accounts of the defensive behavior of *R. septemvittata* have included flight, biting, and expelling musk, but to our knowledge, death-feigning has not previously been described (Layne and Ford 1984. J. Herpetol. 18:496–498; Gibbons and Dorcas 2004. North American Watersnakes: A Natural History. University of Oklahoma Press, Norman. 438 pp.).

We thank the University of Kentucky Department of Forestry, and the Kentucky Department of Fish and Wildlife Resources for support and permits.

CHRISTIAN R. OLDHAM (e-mail: christian.oldham@uky.edu) and **STEVEN J. PRICE** (e-mail: steven.price@uky.edu), Department of Forestry, University of Kentucky, Lexington, Kentucky 40546-0073, USA; **WADE A. BOYS**, Department of Biological and Allied Health Sciences, Ohio Northern University, Ada, Ohio 45810, USA (e-mail: s-boys@onu.edu); **LEO J. FLECKENSTEIN**, Department of Animal and Food Sciences, University of Kentucky, Lexington, Kentucky 40546-0215, USA (e-mail: leo.fleckenstein@uky.edu).

***SISTRURUS CATENATUS* (Massasauga). CLIMBING BEHAVIOR.** A previous study noted six instances of *Sistrurus catenatus* climbing in a shrub-dominated, low-quality habitat (Shoemaker and Gibbs 2010. J. Wildl. Manage. 74:504–513). Those authors proposed that thermoregulation in a basking-site deficient habitat was the motive for this behavior. However, at 1109 h on 25 June 2012 (cloudy, 25.9°C), we observed and documented (Fig. 1) climbing behavior during a mark-recapture survey of *S. catenatus* in the same habitat, which as of 2011 had undergone management efforts by the New York State Department of Environmental Conservation (NYSDEC). The snake was basking ca. 1 m off the ground in a *Vaccinium corymbosum* (Highbush Blueberry) and remained coiled even after our initial approach, at which time we recorded an IR temp of 21.5°C. Upon capture, we noted that this snake was a gravid female (total length = 55.5 cm) initially tagged in 2006. The behavior was observed in habitat augmented by the NYSDEC by cutting vegetation to ground level in 32 plots, each 100 m^2 in area, based on recommendations made by Shoemaker and Gibbs (*op. cit.*). This treatment was followed by cutting of 12 additional 28 m^2 plots in 2012 after field surveys suggested that the rattlesnakes were using cut plots for basking (Johnson 2013. Management and Status of an Endangered Massasauga Rattlesnake Population in New York State. Thesis, SUNY- ESF). Because we observed climbing even after apparently suitable basking habitat had been created, further research is recommended to identify the motivation for this behavior.

I thank Brent Johnson for assistance and photo documention of these observations.

ALEXANDER J. ROBILLARD, State University of New York College of Environmental Science and Forestry, 1 Forestry Drive, Syracuse, New York 13210, USA; e-mail: ajrobill@syr.edu.

***THAMNOPHIS SIRTALIS* (Common Gartersnake). DIET.** On 30 April 2014 we found a *Thamnophis sirtalis* (SVL = 26 cm) beneath a board on an empty block at the corner of Vine St and Mulberry St, Cincinnati, Hamilton Co., Ohio, USA (39.11919°N, 84.51722°W; WGS84). We palpated the snake and it regurgitated an adult *Podarcis muralis* (European Wall Lizard; SVL = 5 cm; Fig. 1). *Podarcis muralis* was introduced to Cincinnati in 1951 from its native range in Europe and has subsequently established satellite colonies in British Columbia, Kentucky, and Indiana (Kraus 2009. Alien Reptiles and Amphibians: A Scientific Compendium and Analysis. Invading Nature: Springer Series in Invasion Ecology. Number 4. Springer, New York. 563 pp.). Within Cincinnati, *P. muralis* inhabits south-facing hillsides flanking the Ohio River and reaches high densities (Brown et al. 1995. Am. Midl. Nat. 133:344–359). Other known predators of *P. muralis* in the USA include *Felis silvestris catus* (Feral Cats; Brown et al. 1995, *op. cit.*) and *Mimus polyglottos* (Mockingbirds; Deichsel and Walker 2010. Herpetol. Rev. 41:228–229). *Thamnophis sirtalis* is a generalist predator, feeding on invertebrates, fish, amphibians, mammals, birds, and small snakes (Rossman et al. 1996. The Garter Snakes: Evolution and Ecology. University of Oklahoma Press, Norman. 332 pp.; Ernst and Ernst 2003. Snakes of the United

PHOTO BY B. JOHNSON

FIG. 1. Gravid female *Sistrurus catenatus* basking in a (~ 1 m tall) *Vaccinium corymbosum* bush.

FIG. 1. *Thamnophis sirtalis* (Common Garter Snake) with a regurgitated *Podarcis muralis* (European Wall Lizard) collected in Cincinnati, Ohio, USA.

States and Canada. Smithsonian Books, Washington, DC. 668 pp.). To our knowledge, this is the first report of *T. sirtalis* preying upon a lizard; the only published report on this topic describes a *T. sirtalis* pursuing (but failing to capture) an Italian Wall Lizard (*Podarcis sicula campestris*) in New York (Mendyk 2007. Herpetol. Rev. 38:82).

CRYSTAL KELEHEAR, Smithsonian Tropical Research Institute, Balboa, Ancon, Republic of Panama (e-mail: crystal.kelehear@hotmail.com); **SEAN P. GRAHAM**, Department of Biology, Geology, and Physical Sciences, Sul Ross State University, Alpine, Texas 79832,USA (e-mail: sean.graham@sulross.edu).

***THAMNOPHIS SIRTALIS TETRATAENIA* (San Francisco Gartersnake). UPLAND HABITAT USE.** Since *Thamnophis sirtalis tetrataenia* was listed as a federally-endangered species in 1967, unpublished descriptions of its natural history suggest that it prefers relatively open upland habitats in proximity to perennial ponds, but this may be the result of observer bias and lack of field study (U.S. Fish and Wildlife Service 1985. Recovery Plan for the San Francisco Garter Snake *Thamnophis sirtalis tetrataenia*. Portland, Oregon; U.S. Fish and Wildlife Service 2006. San Francisco Garter Snake (*Thamnophis sirtalis tetrataenia*) 5-year Review: Summary and Evaluation. Sacramento, California). Recent research detected *T. s. tetrataenia* up to 215 m away from ponds that provide appropriate prey, although no trap-lines were installed at greater distances and the upland consisted primarily of grassland and open scrub to promote managed burning (Halstead et al. 2011. J. Fish Wild. Manage. 2:41–48).

On 19 April 2012 ca. 2.5 km E of La Honda in the Santa Cruz Mountains, San Mateo Co., California, we hand-captured an adult female *T. s. tetrataenia* in mixed hardwood forest with a closed canopy and native understory (37.3159°N, 122.2377°W, WGS84; 459 m elev.). The nearest known population of *T. s. tetrataenia* was at Mindego Lake, situated 450 m E of the site of capture. This pond, located at the margin of a non-native annual grassland and mixed hardwood forest, supported abundant prey, as well as a breeding population of *T. s. tetrataenia*. Based on the date, sex, and distance from the nearest source of prey, the adult female *T. s. tetrataenia* had likely recently emerged from hibernation and was migrating to a seasonal foraging habitat. It was observed within closed-canopy mixed evergreen forest, which has not been documented as a habitat association. The hibernaculum was presumably no less than 435 m from Mindego Lake, and the nearest secondary pond known to support the subspecies was Knuedler Lake, 1.26 km to the southwest. More research is needed to determine the preferred upland habitat associations and the amount of land necessary to support the life cycle of this cryptic snake. *Thamnophis s. tetrataenia* may travel long distances to reach specific microhabitats that provide hibernacula, and it may also benefit from certain vegetation associations to promote dispersal, migration, and predator avoidance.

We are grateful to the California Department of Fish and Wildlife and U.S. Fish and Wildlife Service for issuing permits to support our research. We thank the Midpeninsula Open Space District for access and funding of the field study that provided the opportunity to report this observation.

AARON M. BAUER
Department of Biology, Villanova University
800 Lancaster Avenue, Villanova, Pennsylvania 19085, USA; e-mail: aaron.bauer@villanova.edu

I am especially fond of the history of natural history, including herpetological biography and the history of collections. I am also a sucker for a good type catalogue. *Herpetology in Bonn* has all of this plus it focuses on herpetology in a city that I have known and loved for more than 30 years, so I admit a positive bias. Bonn, the former capitol of the Federal Republic of Germany, is known to many as a herpetological Mecca in Europe and indeed, as described by Kraig Adler in the preface of the book, it is "perhaps the most active herpetological center in Europe." No man is an island but as much as any one institution can owe its reputation to one person, Bonn owes its herpetological fame to Wolfgang Böhme, whose boundless activity and prodigious production of both publications and students transformed Bonn from herpetological backwater to powerhouse.

The book focuses on the history of herpetology in Bonn, especially at the Museum Koenig (ZFMK) and at the University of Bonn. However, it paints a much broader picture of German (and global) herpetology, as Böhme integrates into his narrative the stories of many people whose professional activities intersected with these focal institutions, even if tangentially. The history of herpetology in Bonn predates both the Museum Koenig (opened to the public only in 1934) and the Rheinische Friedrich-Wilhelms University (founded 1818), and begins with the description of a gecko, in 1809, by Dr. Johann Heinrich Crevelt, a personal friend of Bonn's most famous non-herpetologist, Ludwig van Beethoven. For the remainder of the 19th century and into the 20th century, herpetology in Bonn was centered at the University. Among the herpetologists who were associated with the museum were Georg August Goldfuss, a paleontologist and the first to reconstruct fossils, Franz Herrmann Troschel, known to Americans as the describer of *Cophosaurus texanus*, and Franz von Leydig, a prolific anatomist and histologist. However, many other figures made contributions large or small, as students or staff, and all have been captured in this book. They include Johannes Müller, who later gained fame as a faculty member in Berlin, Wilhelm Pflüger, whose *Archiv*, founded in 1868, is the oldest surviving journal in the field of physiology, and Max Weber, who described reptiles from South Africa and Indonesia. Also treated are users of the collections, most notably Giorgio (Georg) Jan, who used snakes from Bonn in his *Iconographie des Ophidiens* (1860–1881).

In the 20th century workers at the university included Wilhelm J. Schmidt, whose numerous papers on the reptile integument remain landmarks, and Fritz Bodenheimer, who left Bonn for Israel and published important herpetological works on Turkey and Palestine. The destruction of Poppelsdorf Castle, home of the zoological museum, in World War II put an end to the importance of the University of Bonn as a site of traditional collections-based herpetological research. However, herpetology has continued to thrive there through the work of Hans Schneider, known for his research on anuran bioacoustics, Steven F. Perry, who has worked extensively on reptile lungs, and Martin Sander, who carries on the long tradition of paleoherpetology in Bonn started by Goldfuss, among others.

The history of herpetology at the Museum Koenig begins with the activities of Alexander Koenig, who grew up in Bonn in the Villa Hammerschmidt, the "White House of Germany" and, until reunification, the primary residence of the German federal president. Koenig was chiefly an ornithologist, but he also collected amphibians and reptiles. Material from his expeditions to Tunisia, Libya, Egypt and Sudan were sent first to Oscar Boettger in Frankfurt and later to Lorenz Müller in Munich for identification. It was not until 1930 that the first herpetological catalogue was initiated at the Museum Koenig (then still a private collection) and not until 1951, when the first herpetologist, Karl Buchholz (1911–1967), was hired. Buchholz worked chiefly in Greece and the Balearic Islands. Greece was also the focus of the second curator Ulrich Gruber, who remained with the small collection for only three years before moving to Munich.

The meteoric rise of herpetology in Bonn began with the arrival, in 1971, of Wolfgang Böhme, a freshly-minted Ph.D. from the University of Kiel, in north Germany. Although his herpetological interests were global, Böhme distinguished himself as an expert in Africa, as well as the Palearctic. He conducted three expeditions to Cameroon in the 1970s, the first in 1973, in the company of Martin Eisentraut, then director of the Museum Koenig. Eisentraut was chiefly a mammologist, but had published extensively in herpetology as well. By the end of the 1970s the herpetological ranks of the ZFMK had grown through the addition of Wolfgang Bischoff, an expert in lacertids from Madgeburg in the then German Democratic Republic, Ursula Bott, Böhme's assistant, and Klaus Busse (ostensibly the ZFMK ichthyologist, but known to herpetologists through his work on Darwin's Frog, *Rhinoderma*).

Growth in the ZFMK collection was augmented by the incorporation of several historical collections from other institutions,

shrewd acquisitions by Böhme that not only enriched Bonn, but saved invaluable material from obscurity and neglect. In 1972, herpetological specimens from the collection of the University of Kiel were obtained in exchange for a neuropteran collection from Bonn. This yielded historically important material from the collection of Friedrich Boie, some of which originated from his brother Heinrich and also Heinrich Kuhl, both of whom died as young men while engaging in the herpetological exploration of Java.

The most important acquisition was that of the Zoologisches Museum of the University of Göttingen in 1977. This collection, rich in types, had been built-up and enriched by generations of curators and donors including Johann Friedrich Blumenbach, Adolph Arnold Berthold, Moritz Wagner, Wilhelm Keferstein, and Jacques von Bedriaga. Göttingen's inclusion in the book has allowed Böhme to discuss important users of this ancient collection, like Johann Gottlob Schneider, Alexander Strauch, George A. Boulenger, Franz Werner, and Willy Wolterstorff, thereby expanding the scope of the volume considerably. This also brings into the book a discussion of the Museum Godeffroy, an institution that sold specimens to museums throughout Europe in the second half of the 19th century. Here I can perhaps resolve a minor mystery outlined by Böhme who mentions (p. 62) a Göttingen specimen of the Fijian iguana, *Brachylophus fasciatus*, supposedly collected by Eduard Graeffe, working for the Museum Godeffroy, in Samoa, where the species is not known to occur. Reference to the now rare published sale catalogues of the Museum Godeffroy reveals that Graeffe visited Viti Levu, Ovalau, Moturiki, Nagarra, Kandavu and the Exploring Group in Fiji and that the single *Brachylophus* for sale came from the "Viti-Inseln" [= Fiji] (Schmeltz 1869). Presumably the same specimen (the same specimen number is listed) appeared in a subsequent catalogue as being from "Viti- u. Tonga-Inseln" [Fiji and Tonga] (Schmelz 1874). If this is the specimen purchased by Göttingen and now in Bonn, the Samoan provenance must be considered an error introduced subsequent to the sale.

More recent acquisitions have included the herpetological collection of the University of Heidelberg (1984), which contained significant historical material and, most spectacularly, the Paul Müller collection of approximately 10,000 specimens, 70% from Brazil, transferred from Saarbrücken within the last decade.

In addition to collection development, the physical arrangement and features of the ZFMK herpetological collection and its live animal facilities are described as are the public exhibits in herpetology. These last are mostly a post-WWII feature of the Museum Koenig, and major modern exhibits with herpetological content, such as a large African savannah exhibit that dominates the ground floor of the museum and a new African rainforest exhibit that is advancing towards completion, were strongly influenced by Böhme.

The growth of the ZFMK collection has been mirrored by a series of type catalogues published over the years. The first (Böhme 1974) listed only 34 names and 22 name-bearing types. Böhme and Bischoff (1984) published a second type catalogue, and a third was prepared in conjunction with Böhme's official retirement (Böhme 2010). The latest type catalogue is included in *Herpetology in Bonn* as Chapter 4. This incarnation includes 663 herpetological types, 337 of them name-bearing.

Although type catalogues are often considered mere compilations, simply copied from museum records, this is a naïve view, held only by those who have never written one. A good type catalogue, and this is a good one, provides a wealth of historical and taxonomic information relevant to the specimens discussed. Indeed, sometimes an individual account can spiral out into the equivalent of a separate paper. Some entries are hugely detailed, including those for *Megophrys montana* Kuhl and van Hasselt, 1822 and *Calamita punctatus* Schneider, 1799—the latter three pages long and illustrated with five photos.

Accounts in the type catalogue give original publication, specimen number, collector, date, and comments on types other collections, current name, and recent relevant systematic or distributional information. A section on lost or missing types is also provided. These comprise only 10 amphibians and 13 reptiles, chiefly from the historical collection of Göttingen, such as the type of *Acanthosaurus gibbosus*, Berthold, 1846, a long forgotten synonym of *Moloch horridus*. A more modern lost specimen is the holotype of *Kinyongia vanheygeni* Nečas, 2009, which was stolen in a car break-in after its ZFMK registration number was assigned, but before it reached the museum!

The catalogue is a rich source of information and reflects Böhme's scholarship and his broad and deep knowledge of nomenclature, history, and all things herpetological. The catalogue of extant types includes material representing 18 nominal salamander taxa, 230 frogs, two caecilians, eight turtles, two crocodylians, 76 snakes, and 331 lizards (dominated by gekkotans – 110; lacertids – 72, skinks – 39, and chameleons – 31). Interestingly, a paratype of *Gallotia intermedia*, ZFMK 62798, was still alive at the time of writing. Among the most noteworthy nomenclatural actions taken in the catalogue is the designation of a lectotype of *Scincus laticeps* Schneider, 1801 (= *Plestiodon laticeps*), one of two original types cited by Schneider and derived from the Göttingen collection.

A list of types by source countries reveals 74 nations of origin, with Madagascar represented by the greatest number of types (64) followed by Indonesia and Vietnam with 20 each, and Spain, Iran, and Colombia close behind. Modern sources of types include many former and current ZFMK students and associates, but also specimens used by other workers from across Germany and Europe and around the world. From the 1990s onward it has largely been students driving the growth of the collections and the regions and taxa of strength, both among the types and in the collection in general, reflecting themes in Böhme's research and that of his students.

The lasting influence of Böhme on herpetology is really shown in a section of the book focusing on teaching and education. He has taught courses at the University of Bonn and for more than 40 years has led a legendary annual field course to Neusiedlersee in Austria. Böhme mentored 142 diploma and masters students and 46 doctoral students, most of them dealing with herpetological themes. Many of these, including Frank Glaw, Thomas Ziegler, Jörn Köhler, Miguel Vences, Andreas Schmitz, Thomas Wilms, Philipp Wagner, André Koch, Dennis Rödder, and Claudia Koch (the last two his successors at the ZFMK), completed two advanced degrees with him. Others students (doctoral degree only with Böhme) have included Mathias Lang, Frank Brandstätter, Mark Auliya, and Nguyen Quang Truong. Numerous postdocs, visiting students, and others have also benefited from Böhme's mentorship and support in Bonn. These include: Scott Moody (USA), Abidin Budak (Turkey), Charles Klaver (Netherlands), Zbigniew Szyndlar (Poland), David Tarkaschvilli (Georgia), and Khalid Baig (Pakistan). For each of these mentees a synopsis of their published works and current positions are provided. Collectively these students—and their

students—have had a tremendous impact upon herpetology in Europe and beyond. They include professors, curators, and institutional directors from across Germany and in other parts of the world.

Another chapter of the book summarizes the organizations associated with the ZFMK and the symposia held there. The Museum Koenig has hosted a series of Tropical Symposia and Varanid Symposia, as well as conferences devoted to agamid lizards, *Zootoca vivipara*, and the herpetology of the Canary Islands. Of greatest importance, however, are the meetings of the DGHT (Deutsche Gesellschaft für Herpetologie und Terrarienkunde) and the SEH (Societas Europaea Herpetologica). The foundational meeting of the latter was held in Bonn in 1979 and Böhme vividly describes the birth of this pan-European society and provides photos of the historic event. The SEH Ordinary General Meetings were subsequently held in Bonn twice, in 1995 and again in 2005, whereas the annual DGHT meetings were hosted in 1977, 1991, 2013, and 2014. The centrality of Bonn for these societies is no accident; Böhme has held both the chairmanship of the DGHT and the presidency of the SEH and for a number of years the DGHT was based in Bonn, with Wolfgang Bischoff serving as editor of its flagship journal, *Salamandra*.

Literature citations in *Herpetology in Bonn* are distributed throughout the chapters and, in all, approximately 1250 references are cited. These serve as a portal to many fascinating publications, many of which will be unfamiliar to American readers. Indeed, I have been working my way through the references, copying or downloading those I am lacking. The citations are wonderfully complete as well—a bibliographer's dream. I noted only one incomplete citation (pagination is lacking for Blumenbach 1779).

There is little to complain about in this book, but I will note a few minor issues, most of which are probably the result of the fact that the book was produced on a tight schedule to allow it to be released in conjunction with the 50th anniversary meeting of the DGHT in October 2014. The English is especially good early in the volume, additional rounds of language proofing were foregone for the rest of the book, so native speakers may find a few awkward phrases, although everything is, of course, fully comprehensible. For example on page 57 "prices" should be "prizes."

There are just a few minor inconsistencies and typographical errors scattered through the text. On page 39 the year of Karl Buchholz's death is given as 1964 (it is correctly noted as 1967 elsewhere) and on page 65 Ferdinando Sordelli's year of birth is given as 1937 (instead of 1837). On page 72, the date of donation of the Paul Müller collection is given both as 2008 and 2010. On page 143, the degree signs (°) in the geographic coordinates for *Echinosaurs brachycephala* appear to be represented by "E"s. Contrary to the implication on page 62, the journal *Brimleyana* was neither founded nor run by the Brimley brothers. It was started in 1979, long after the death of the Brimleys, both of whom died in 1946.

A few additional features would have been handy in the type catalogue. First, I always prefer that type catalogues provide the verbatim type localities, set off in quotes. This is done in some instances, but not consistently. There is also some inconsistency in the listing of current names, if different from the original names. These are generally provided in the "Comment" section of each account, but there are a few exceptions, e.g., *Cyrtodactylus kotschyi* subspecies (p. 136) are currently placed in *Mediodactylus*. Likewise, taxa described with trinomials, but now regarded as specifically distinct, are not noted as such. A separate bold header for current names in the accounts and alphabetized cross references to these names would also have been useful (although admittedly this adds space and current names are liable to change).

Who should buy this book? This is a book that has something of relevance for anyone working on any of the hundreds of taxa represented by types in the ZFMK collection. It is also a book for anyone with even the slightest interest in the history of herpetology. Along with Rieck et al. (2001), this book is an essential tool for understanding the history of German herpetology, and, with the volumes of *Contributions to the History of Herpetology* (Adler 1989, 1995, 2012, 2014), it will be a critical resource for the history of herpetology more globally. Indeed, by providing a single-authored narrative of the interconnectedness of researchers, collections, and institutions it complements these sister works, in which history is told chiefly through separate personal or institutional biographies. Finally, for the literally thousands of herpetologists worldwide who have interacted in some way with Wolfgang Böhme over the years, this book provides a fitting memento of a unique personality and an incredible (and still vibrant) career. The book ends with a short "Outlook and epilogue" chapter about the future of herpetology in Bonn. Regardless of future prospects, one thing is certain—there will never be another Böhme.

e-mail: williamroybranch@gmail.com

This well-produced book, herein referred to as *Girdled Lizards*, forms yet another part of the excellent series of specialist herpetological monographs published by Chimaira. Girdled lizards and their relatives comprise the Cordylidae, armored scincomorph lizards endemic to Sub-Saharan Africa. The family includes two subfamilies and 10 genera, with 80+ recognized taxa (Stanley et al. 2010 and subsequent updates), with the majority of diversity and endemicity occurring in southern Africa, particularly South Africa (50 taxa, 70% endemic). Its members display a wide variety of morphologies, life histories, and behaviors, and have been the subject of numerous recent studies in South Africa (see accounts in Bates et al. 2014 and references therein). Most studies have been directed at the Cordylinae, a group of viviparous, mainly small (maximum SVL *Smaug giganteus* 145 mm), sedentary ambush predators. These characteristics make them ideal candidates for the international pet trade and captive husbandry, and due to concern and perceived threats from the international pet trade to a number of charismatic cordylids (e.g., the Armadillo Girdled Lizard *Ouroborus cataphractus* and Giant Girdled Lizard *S. giganteus*), all *Cordylus* and *Pseudocordylus* species are placed on CITES Appendix 2 (Broadley 2006). This bulk listing has always been controversial as many cordylids are conspicuous components of the Cape herpetofauna, and are among the commonest lizards in the region. The majority of species are of Least Concern (Bates et al. 2014) and the inclusion of all of these unthreatened species on CITES was at best inaccurate, at worst lazy. Moreover, the existing CITES list is now compromised by taxonomic adjustments (Stanley et al. 2011), and also by the most recent conservation assessments that have lowered the threatened status of many of the southern taxa. For instance, the perceived threat of unsustainable collecting for the pet trade of *O. cataphractus* has never been substantiated and the species was, therefore, recently downgraded from Vulnerable (IUCN 2014) to Least Concern in the latest iteration of the South African Reptile Red List (Bates et al. 2014).

The numerous recent research studies on cordylids have resulted in new understanding of phylogenetic relationships, distribution, ecology, behavior, etc., and the time was ripe for a synthetic family summary such as *Girdled Lizards*. However, it is important to note at the outset that despite its title *Girdled Lizards* does not include all cordylids, for it excludes the subfamily Platysaurinae (15 species, 29 taxa) and also the cordyline Grass Lizards (*Chamaesaura*; five species, six taxa). The former includes the oviparous Flat Lizards (*Platysaurus*), famed for their dorsoventrally depressed bodies and the use of stunning sexual dichromism by males in both territorial and mating displays. Grass lizards comprise a small group of elongate, snake-like lizards with long tails and minute limbs; a body form that allows them to move rapidly in long grass and other short vegetation. Why these two genera are excluded from the book is not explained and their omission certainly diminishes the value of *Girdled Lizards*, for these genera exhibit the most extreme morphological specialization and, perhaps, the most interesting biology. Admittedly there have been relatively few ecological studies on grass lizards, but flat lizards are relatively well known following the taxonomic studies of Don Broadley (1978) and the extensive studies of platysaurine ecology and behavior by Martin Whiting and his colleagues and students (see summaries and references in Whiting 2014). Much of this research focused on Broadley's Flat Lizard (*Platysaurus broadleyi*), a delightful species that lives in dense colonies and which "may be unique among lizards because males have an ultraviolet-reflective throat used to signal fighting ability" (Whiting et al. 2006).

Girdled Lizards starts with a Preface by Aaron M. Bauer, followed by a Natural History section. This includes a short Introduction of three pages, two comprising some of the earliest illustrations of cordylid lizards. After a six-page summary of recent developments in the systematics and evolution of the Cordylidae (reviewed by Ed Stanley on whose studies it is based) there are two pages of maps and a three-page tabulation of all cordylids by country. The latter illustrates the extraordinary diversity of the family in the subcontinent. A summary of the Great Describers lists the species named by the three leading historical herpetologists of southern Africa, namely Sir Andrew Smith (1797–1872, 8 species), Vivian FitzSimons (1901–1975, 11 taxa), and Donald Broadley (1932–present, 13 taxa). The wording of the text is ambiguous as it suggests that all the cordylids these authors described are still valid, whereas this is true only of Don Broadley. Both Smith and FitzSimons described taxa that are now placed in synonymy (Smith, three taxa: *Cordylus nebulosus* Smith 1838 = *Ouroboros cataphractus*; *Cordylus algoaensis* Smith 1838 = *Pseudocordylus microlepidotus fasciatus*; *Cordylus* (*Pseudocordylus*) *montanus* Smith 1838 = *Pseudocordylus microlepidotus microlepidotus*); FitzSimons, two taxa: *Zonurus laevigatus* FitzSimons 1933 = *Smaug depressus*; *Zonurus vandami perkoensis* FitzSimons, 1930 = *Smaug vandami*).

The Species Accounts, which form the heart of the book, present a comprehensive summary of the species previously assigned to the genera *Cordylus* and *Pseudocordylus*. Genera are arranged in alphabetical order, as are the species within them. There are useful keys to the new genera, as well as for species within each genus. A table lists old and new scientific names, as well as English and German common names. Each genus has a short introductory summary, followed by the detailed species accounts. These are arranged with common headings, i.e., Synonyms, Etymology, Type Locality, Type Publication, Type Deposition, Description, Colour, Size, Reproduction, and Distribution and Habitat. The latter sections are somewhat terse and do not summarize much of the detailed ecological studies that are available for many species. For over 20 years the Mouton group (Stellenbosch University) has published numerous ecological and behavioral studies on the *Cordylus codylus-niger* complex, *Karusosaurus polyzonus*, and more recently *Ouruborus cataphractus* (e.g., Mouton and van Wyk 1997; Mouton 2011). Incorporation into the species accounts of more details from these studies would have given greater insight into the lives of these interesting groups. An additional perplexing oversight in these accounts

is the lack of a conservation section as many are threatened (e.g., Vulnerable: *Hemicordylus nebulosus* and *Smaug giganteus*; Near Threatened: *Cordylus imkeae, C. macropholis, C. niger, C. oelofseni, Pseudocordylus langi, P. spinosus*, and *P. transvaalensis*).

A comprehensive (40-page) section on Keeping and Breeding these fascinating lizards follows the Natural History section. It has lots of practical advice for captive husbandry and terrarium design, but would benefit from at least some suggestions for disease treatment and control. Admittedly these are technical and complex issues, but the reader would benefit from direction to at least relevant and accessible literature. Finally the book finishes with a one-page list of Museum Details, which lists 14 examples. These are somewhat arbitrary, as it is not obvious why in the USA the Centennial Museum and Gardens, University of Texas should be included in preference to the American Museum of Natural History, New York, while in South Africa, the KwaZulu Natal Museum, Pietermaritzburg is listed (when it has only a minor collection and no herpetologist) in preference to the National Museum, Bloemfontein (with a thriving Herpetology Department, and the fourth largest herpetological collection in the subcontinent!). More useful is Table 4, a synopsis of variation in scalation of all species discussed. A six -page Bibliography gives direction for the major literature on the topic.

With the current intensity of revisionary and phylogenetic studies on southern African reptiles it is little wonder that a number of taxonomic adjustments have occurred in the year subsequent to the release of *Girdled Lizards*. These include a revision of the *Smaug warreni* complex (Stanley and Bates 2014), with the elevation of the three subspecies of *S. warreni* to specific status; i.e., *S. warreni* (Boulenger, 1908), *S. barbertonensis* (Van Dam, 1921), and *S. depressus* (FitzSimons, 1930). A putative new species within *S. warreni* has been signaled (Stanley and Bates 2014), as have additional new lineages within the East African and Angolan *Cordylus* radiations (Branch, Bates, and Stanley, unpubl. obs.). A consequence of the reevaluation of *S. warreni* material previously assigned to other taxa within the complex is that some maps in the *Girdled Lizards* species accounts, and those in the recently launched *Atlas and Red List of the Reptiles of South Africa, Lesotho and Swaziland* (Bates et al. 2014), need readjustment. Stanley and Bates (2014) noted that early records from Blouberg/Makgabeng and farm New York (Jacobsen 1989), previously considered as isolated populations of *S. vandami*, are referable to *S. breyeri* despite confusing coloration in some cases. Sympatry between these two species, therefore, remains unconfirmed as their presently understood ranges do not overlap.

In summary, and despite its constrained coverage, *Girdled Lizards* is a very useful reference. It covers most cordyline genera and documents the diversity and distribution of some of Africa's most interesting and popular lizards. The author, his photographic collaborators, and the publishers are to be congratulated on the preparation of this useful, beautifully illustrated, and informative book.

Guyana is one of these countries that some may find hard to locate on a map. "Is it in Africa?" or "is it an island?" are common questions when Guyana is mentioned in a casual conversation. Guyana is part of the Caribbean Community and Common Market (CARICOM), which makes things even more confusing because geographically the country is not related to the Caribbean. The Co-operative Republic of Guyana—not to be confounded

with French Guiana (northern South America) or Guinea (western Africa)—is a former British colony that gained its independence in 1966. The country lies along the Atlantic Coast of northeastern South America, between Suriname to the east, Venezuela to the west, and Brazil to the south, and is part of the Guiana Shield biogeographical region. Guyana is fascinating in many ways, from its rich ethnic and cultural diversity (e.g., Levinson 1998) to its extensive pristine forest cover (ca. 18.39 million ha, thus about 85% of the country; Bholanath et al. 2012) and still—but for how long?—well-preserved biodiversity.

Prior to the publication of *Amphibians and Reptiles of Guyana* there was no book or field guide treating the herpetological diversity of Guyana as a whole. The very few existing compendia merely covered amphibians from restricted areas, e.g., Kaieteur National Park (Kok and Kalamandeen 2008) and Mount Ayanganna (MacCulloch and Lathrop 2009). The opus by Cole et al. is, therefore, a long-awaited handbook, not only for researchers working in Guyana, but also for naturalists interested in the region, as well as locals interested in their herpetofauna. Because the authors have all been working on the herpetofauna of Guyana for a long time (sometimes decades), we started reading *Amphibians and Reptiles of Guyana* with great expectations. We are pleased that they were satisfactorily met.

Although *Amphibians and Reptiles of Guyana* can be obtained as a paperback book, it actually is a long article published in Volume 125(4) of the *Proceedings of the Biological Society of Washington*. At the time it was downloaded by PJRK (16 February 2013), the PDF available from BioOne did not include the Contents (pages i–ii) or the Dedication (page iii). The lack of a table of contents in the PDF makes it less easy to use than the printed version. The one-page Dedication was downloadable for an additional $10.00, which sounds quite prohibitive for a less than half-page paragraph. Guyana is the third poorest country of South America (after Bolivia and Paraguay), and $25.00 could be crippling to most Guyanese who are interested in identifying their herpetofauna and want to learn more about it. We heard from the authors that making the PDF free was not possible for copyright reasons, but that several tens of hard copies were sent to Guyana by Charles J. Cole (hereafter CJC) in order to be distributed to students, scientists, and other interested people, including ones in other countries in South America (CJC, pers. comm. to PJRK, Feb. 2013).

Amphibians and Reptiles of Guyana is printed on high quality paper and should resist some mistreatments while being carried out into the field, except maybe for the binding, which is of lower quality. The book is written in very clear English and is readily accessible even to the uninitiated, maybe except for the Key section. The number of misspellings is extremely low for such a long text.

After a two-page abstract, the book offers a 14-page introductory section, which contains four main sections, as follows: Introduction, Methods, Abbreviations of Scientific Collections Used, and Identification of Specimens. These sections provide the reader with a good overview of what the book is offering, and how to use it properly.

The introductory section is followed by a 37-page section containing dichotomous identification keys. High-quality drawings, arranged in five figures (figs. 5–9), are used to highlight characters that could be difficult to visualize for some less experienced readers. The key was extensively used in the field and in the laboratory by several of PJRK's students, and these drawings proved to be useful for those not yet acquainted with all the terms used. In addition to the drawings, some characters are briefly described within the key (e.g., apical pits, ventral scales). This proved to be useful most of the time, but we sometimes regretted the lack of precision in the description of some characters. Ventral scales for instance are described as "wide belly scales from neck to vent," which in our opinion is too imprecise to allow unambiguous comparisons. It would have been better to provide a drawing showing exactly how ventral scales should be counted (e.g., following the method of Dowling 1951).

Some text is added to provide the reference(s) on which a specific identification key section is based, occasionally to provide additional helpful advice to the reader. The Key section proved to be helpful, we only found a few mistakes or weak points in that part of the book:

Key step 6 (p. 332): the possession of "conspicuous toad-like parotoid glands" leads to *Atelopus spumarius*, which lacks such glands.

Key step 21a (p. 335): the possession of a "translucent to transparent belly skin in adults" leads to Centrolenidae or Allophrynidae, while this character is also shared with *Hypsiboas cinerascens* (Spix, 1824) and *H. ornatissimus* (Noble, 1923), which are in Hylidae. An additional step should have been added here to avoid confusion.

Key step 19 (p. 343), step 3 (p. 346) and step 9 (p. 347): maximum body length of adult frogs. This is obviously a useless character when only a juvenile is at hand, and this proved to be a weak point of the key in the field when used by students.

Key step 40b (p. 345) mentions "maximum adult body length 37–50 mm." However, to reach step 40, one has to go through step 38a (p. 345) that specifies "maximum adult body length 32–42 mm. "

The Key section is followed by the largest segment of the book, the species accounts (approximately 160 pages). Seven of the 324 amphibian and reptile species reported from the country were added after completion of the text and are listed in the Appendix 1 (p. 574). We found the way each species is presented very clear and the information provided highly valuable. Each taxon account begins with the scientific name of the species, the authorship, and the number of the plate(s) illustrating the species, when available. This is followed by a few paragraphs named as follows: Type Material (which we found very handy), Distribution (global), Vouchers for Guyana (again a very useful section referring to all Guyanese material identified in collections by the authors), Coloration in Life, and sometimes an additional paragraph named Comments where the authors provide some additional information, e.g., on the taxonomic status of the species, its ecology, or its peculiar morphology.

The exotic invasive *Trachemys scripta* (Thunberg in Schoepff, 1792) is not listed for the country although the species has been reported from Guyana by Lever (2006) (see comment in Meilink et al. 2013).

At least three taxonomic rearrangements appeared before the book was published and were not followed, nor commented upon, by Cole et al. (2013). We heard from the authors that these changes actually occurred after the manuscript was finalized and going to press (CJC, pers. comm. to PJRK, 17 Jan. 2015). These rearrangements are:

The erection of a new genus, *Amazophrynella* Fouquet, Recoder, Teixeira, Cassimiro, Amaro, Camacho, Damasceno, Carnaval, Moritz, and Rodrigues, 2012, for the Amazonian species formerly in *Dendrophryniscus* Jiménez de la Espada, 1870 by Fouquet et al. (2012a, b). *Dendrophryniscus minutus* (Melin, 1941) (p. 375)

should thus have been better treated as *Amazophrynella minuta* (Melin, 1941).

The revalidation by Hedges and Conn (2012) of the genus *Copeoglossum* Tschudi, 1845 and the family Mabuyidae Mittleman, 1952, in which *C. nigropunctatum* (Spix, 1825) is placed on the basis of morphological and molecular data. The species is still treated as *Mabuya nigropunctata* (Spix, 1825) in the family Scincidae Oppel, 1811 in Cole et al. (2013: 463).

The synonymization of *Bothriopsis* Peters, 1861 with *Bothrops* Wagler, 1824 by Fenwick et al. (2009), who confirmed *Bothrops* to be paraphyletic with respect to the genus *Bothriopsis*. *Bothriopsis bilineatus* (Wied-Neuwied, 1821) and *B. taeniatus* (Wagler, 1824) (p. 519) should therefore be treated as *Bothrops bilineatus* and *Bothrops taeniatus*, respectively.

We detected a few taxonomic issues that are not mentioned in the species accounts (some for the same reason explained above):

Oreophrynella dendronastes Lathrop and MacCulloch, 2007 (p. 376) was shown by Kok et al. (2012, in their suppl. info.) to likely be a synonym of *O. macconnelli* Boulenger, 1900.

Stefania ackawaio MacCulloch and Lathrop, 2002 (p. 395) was shown by Kok et al. (2012, in their suppl. info.) to likely be a synonym of *S. roraimae* Duellman and Hoogmoed, 1984. Specimens of *S. ackawaio* have apparently been misidentified with *S. roraimae* and *S. woodleyi*, as shown in the phylogenetic tree provided in Kok et al. (2012, suppl. info.).

The mention of *Stefania scalae* Rivero, 1970 (p. 398) from Guyana is based on a single specimen collected on Mount Ayanganna at 1550 m elevation (ROM 39470, MacCulloch and Lathrop 2002). However, Kok et al. (2012, suppl. info.) showed that ROM 39470 was misidentified, and is actually *Stefania evansi* (Boulenger, 1904). Therefore, although *Stefania scalae* is likely present in western Guyana, its actual presence in the country still needs to be confirmed.

Hypsiboas sp. (Kok and Kalamandeen 2008: 176) is not treated in the book although it is a valid taxon, even if still undescribed. *Hypsiboas* sp. could have been treated in the species accounts as the authors did with *Microcaecilia* sp., and the species should be added to the country list.

Some taxonomic changes occurred after the book was published. These mostly concern:

Allobates spumaponens Kok and Ernst, 2007 (p. 370): the species was considered a synonym of *A. sumtuosus* (Morales, 2002) by Simões et al. (2013). *Allobates spumaponens* should therefore be removed from the list of species endemic to Guyana (p. 546).

Ceuthomantis Heinicke, Duellman, Trueb, Means, MacCulloch and Hedges, 2009 and Ceuthomantidae Heinicke, Duellman, Trueb, Means, MacCulloch and Hedges, 2009 (p. 385): Padial et al. (2014a) revised the systematics of terraranas and transferred *Ceuthomantis* to Pristimantinae Ohler and Dubois, 2012 (subfamily of Craugastoridae). Shortly thereafter, Padial et al. (2014b) realized that Ceuthomantidae actually has priority over Pristimantinae. Therefore, Ceuthomantinae is the correct subfamily name for *Ceuthomantis*.

Osteocephalus cabrerai (Cochran and Goin, 1970) (p. 410): the correct name for that species in Guyana is *O. helenae* (Ruthven, 1919) as demonstrated by Jungfer et al. (2013).

"*Hyla*" *warreni* Duellman and Hoogmoed, 1992 (p. 402): this taxon belongs to the genus *Tepuihyla* as shown in Kok et al. (2012, suppl. info.) and confirmed by Jungfer et al. (2013). The correct species name is therefore *Tepuihyla warreni* (Duellman and Hoogmoed, 1992).

Osteocephalus exophthalmus Smith and Noonan, 2001 (p. 410): this taxon belongs to the genus *Tepuihyla* as shown in Jungfer et al. (2013). The correct name for that species is thus *Tepuihyla exophthalma* (Smith and Noonan, 2001).

Osteocephalus phasmatus MacCulloch and Lathrop, 2005 (p. 412): this taxon belongs to the genus *Tepuihyla* as shown in Jungfer et al. (2013), who demonstrate that it is a synonym of *Tepuihyla exophthalma* (Smith and Noonan, 2001). *Osteocephalus phasmatus* should therefore be removed from the list of species endemic to Guyana (p. 546).

Scinax trilineatus (Hoogmoed and Gorzula, 1979) (p. 417): the species was synonymized with *S. fuscomarginatus* (Lutz, 1925) by Brusquetti et al. (2014).

Tepuihyla talbergae Duellman and Yoshpa, 1996 (p. 418): the species was synonymized with *T. rodriguezi* (Rivero, 1968) by Jungfer et al. (2013). *Tepuihyla talbergae* should therefore be removed from the list of species endemic to Guyana (p. 546).

Chiasmocleis jimi Caramaschi and Cruz, 2001 (p. 430): the species is considered a synonym of *C. hudsoni* Parker, 1940 by Peloso et al. (2014).

Caecilita iwokramae Wake and Donnelly, 2010 (p. 438): the species, originally described as lungless, was later shown to have lungs, and the genus *Caecilita* was synonymized with *Microcaecilia* Taylor, 1968 by Wilkinson et al. (2014). The correct name for that species is thus *Microcaecilia iwokramae* (Wake and Donnelly, 2010).

Riolama leucosticta (Boulenger, 1900) (p. 457): Cole et al. (2013) emphasized that the type locality of that species is in Venezuela, not in Guyana, and that voucher specimens having localities unambiguously located in Guyana are lacking. Kok (2015) formally reports the species from Guyana based on populations from Wei-Assipu-tepui and Maringma-tepui, Cuyuni-Mazaruni District.

Pseustes sulphureus (Wagler, 1824) (p. 506): the species was reallocated to the genus *Spilotes* by Jadin et al. (2013). The correct name for that taxon is therefore *Spilotes sulphureus* (Wagler, 1824).

Rhinobothryum Wagler, 1830 (p. 506): the genus is considered monotypic by Cole et al. (2013), who state that *R. bovallii* (Andersson, 1916) is recognized as a junior synonym of *R. lentiginosum* (Scopoli, 1788) (erroneously reported as Scopoli, 1785 in Cole et al. 2013). However, this was in error as there is no such statement in the literature (CJC, pers. comm. to PJRK, 7 January 2014).

Microcaecilia savagei Wake and Donnelly, 2013 was recently described from Iwokrama, Guyana (Donnelly and Wake 2013), and should be added to the country list. It should also be added to the list of species endemic to Guyana (p. 546).

The authors frequently refer to McDiarmid et al. (1999) for snake taxonomy and/or geographic references, it should be noted that a more recent and comprehensive publication is now available (Wallach et al. 2014).

As the title suggests, the section following the species accounts mainly deals with biogeography. That Discussion section covers 17 pages. The authors mainly discuss sampling issues (most areas having been clearly undersampled) then compare sites within Guyana, based on elevation. Seven lowland sites are compared, as well as three isolated highland sites. Lowland versus isolated highland sites are compared as well. A list of endemic species is provided on pp. 546–547. That list actually represents the species having their type locality in Guyana; some of them have much wider distributions (e.g., *Allophryne ruthveni* Gaige, 1926, *Leposoma guianense* Ruibal, 1952, and *Gonatodes annularis* Boulenger, 1887, to cite a few). After a few comments

about endangered species, the section ends with a useful Summary and Conclusions paragraph, stressing that much work still needs to be done in the area.

The next section, which follows the Acknowledgments (3 pages), the Literature Cited (22 pages), and the two appendices (5 pages), covers 41 pages and comprises the color plates. The book's Abstract (p. 317) and Plate Legends (p. 580) both mention that 62% of the amphibian and reptile species known to occur in Guyana are illustrated. However, we actually counted 192 species being illustrated, which corresponds to 59.3% of the total number of species. Photographs of 15 species (4.6% of the total number of species, 7.8% of the species illustrated) are from outside Guyana, in which case the exact locality is specified. This is important because some might later prove to be distinct species. Among the 229 color figures, about 1/4 are of obviously freshly euthanized animals, and 125 are taken on a white background (54.6%) instead of natural habitat. This is never problematic, and we found the vast majority of the photographs to be of very good to sufficient quality to help with species identification. However, the authors should have specified in the plate captions when the figure illustrates a juvenile specimen. Indeed, for some species there is an ontogenetic change in coloration (as mentioned in the species accounts) and the reader could be misled by the figure, e.g., *Chironius scurrulus* (Wagler, 1824), plate 30D, p. 610 (adult color pattern shown in Starace 2014); *Mastigodryas boddaerti* (Sentzen, 1796), plate 32E, p. 612 (adult color pattern illustrated in Starace 2014); *Pseustes poecilonotus* (Günther, 1858), plate 34E, p. 614 (adult color pattern shown in Starace 2014). Mentioning the page number of the corresponding species account in the figure caption would have been helpful to readers who check the color photographs first.

In many cases we found the absence of any illustration, e.g., *Dendrobates tinctorius* (Cuvier, 1797), *Ceratophrys cornuta* (Linnaeus, 1758), *Clelia clelia* (Daudin, 1803), *Siphlophis cervinus* (Laurenti, 1768), or the lack of illustration of a specimen of Guyanese origin, surprising because either it seems very unlikely that such a photograph was not available, and some of these species are already illustrated by Guyanese specimens in the literature, *e.g.*, *Anomaloglossus praderioi* (La Marca, 1998) (not 1997 as stated by the authors), *Hyalinobatrachium taylori* (Goin, 1968), *Scinax boesemanni* (Goin, 1966) and *Oxyrhopus occipitalis* (Wagler, 1824) to cite just a few (in Kok 2010; Kok and Castroviejo-Fisher 2008; Kok and Kalamandeen 2008; MacCulloch et al. 2009, respectively). It should, therefore, have been possible to provide one. But these are rather minor criticisms, and maybe the authors were limited by space. The caption of *Phimophis guianensis* does not mention any locality; it should be Dubulay (DUB) according to the text.

To conclude, we found *Amphibians and Reptiles of Guyana* to be very well written, extremely useful, nicely illustrated, and we highly recommend it to anyone interested in the Neotropical herpetofauna.

Acknowledgments.—PJRK is grateful to 2013–2014 Master 2 students of the Vrije Universiteit Brussel, Belgium (VUB) for constructive discussions about the identification keys. We thank Jay Cole for providing useful information.

The Symbol: Wall Lizards of Ibiza and Formentera

Nathan Dappen, Neil Losin, and Valentin Pérez-Mellado. 2013. Day's Edge Productions (www.daysedgeproductions.com/the_symbol/). Softcover. 128 pp. US $19.99.

AARON M. BAUER
Department of Biology, Villanova University, 800 Lancaster Avenue, Villanova, Pennsylvania 19085, USA; e-mail: aaron.bauer@villanova.edu

The Symbol is a small, four-language book (Spanish, English, Italian, German) that sings the praises of the Ibizan Wall Lizard (*Podarcis pityusensis*). While perhaps not a household name in America, this attractive lacertid is indeed emblematic of the islands of the Pityusic Archipelago (in the western Balearic Islands of Spain), of which Ibiza is the largest and most well-known. In addition to being conspicuous throughout the archipelago, it is the only native, non-volant vertebrate in the archipelago.

The book is beautifully illustrated by many images of this photogenic lizard and its equally attractive habitat. That the lizard is indeed a symbol of the islands is attested by photos of many lizard logos on everything from tee-shirts to shops to tattoos (although many seem to depict geckos!). In addition to nice portrait shots, there are wonderful images of male/male combat, copulation, as well as feeding (on everything, including plant material).

The text is quite short, as it needs to be given that it must be repeated in four languages (in four columns spread across facing pages). Some basic information about lizards in general is provided, but the majority of the book is devoted to *P. pityusensis*. The information is mostly relatively elementary and is organized by questions, the first of which is "What is the current classification of the species?" The geological backdrop to the evolution of the lizard is provided as is basic taxonomic information. Although subspecies are not widely accepted in North American herpetology today, they remain in use in Europe and are a legacy of both different ways of thinking about what a species is and of the in-depth study of a relatively limited fauna. The Pityusic wall lizard has had 45 subspecific forms named—the majority of which were described by German herpetologists, 23 of which are now generally recognized and listed in this book. The occurrence of these on the various islands in the group, most of which are tiny and cluster around Ibiza or the smaller Formentera, is shown on a map, although the island names are not given. At least five of the forms are illustrated, including the especially colorful lizards of Es Vedrà, with bright blue flanks and orange-yellow backs. In some cases the lizards are named, but in others one must guess or at least consult a map to see which species are on which island. The book is clearly not meant for systematists, but more for those wishing to appreciate the lizard they saw while living it up during Ibiza's raucous high season.

Other sections of the book treat thermoregulation, habitat, seasonal activity, communication, aggression, and reproduction. Some useful information is provided, but some questions, like "do these lizards have multiple clutches per year?" that might occur to readers are not addressed. There is a moderately extensive discussion of the role of color in sexual selection and the ontogeny of color, as one would expect with such extravagantly hued lizards. The book advocates for the conservation of these lizards, which are considered vulnerable. This might seem to be contradicted by the statement that the lizards occur at densities of thousands per hectare. However, the overall small area occupied by the species, and especially by the subspecies, if these are treated as separate conservation units, is the explanation for their conservation status.

In general the information provided is accurate and clearly presented. However, it is stated that male lizards (in general) are almost always larger than females (p. 28), whereas Fitch (1981) found that females were as large or larger than males in 36% of the 408 lizard taxa he considered. My only other minor quibbles are that the term "hemipene" is used in place of hemipenis (p. 28) and that the date of description of the focal species is variously given as 1883 (p. 46) and 1884 (p. 48)—it is actually 1883.

The book closes with a two-page spread of short biographies

of the three authors. The first two authors, who also took the stunning photos, may not be familiar to herpetologists, but Valentin Perez-Mellado will be familiar to those who know the Spanish insular herpetofauna. The book was financed through a Kickstarter campaign. Its success suggests that the authors' love for *the symbol* is widely shared. There is a downside to this type of support for a book, however, at least for bibliographers: the book has no stated publisher, city of publication, and no ISBN number. Neither is a date of publication printed in the book (although it is 2013).

A trained herpetologist will not learn much new from the book (for the most up-to-date summary of more technical information about the Ibizan Wall Lizard see Salvador 2014), but an amateur naturalist might and anyone who picks it up will gain an appreciation for the diversity in one species and will wonder about how and why intraspecific diversity is so great in this species.

The charismatic North American tortoises hold a special place in our culture and natural history. Despite the perseverance of these tortoises over millions of years, biologists now question their ability to persist into the future. In light of documented declines, habitat loss, and numerous threats to tortoise populations, the editors gathered a diverse group of researchers to review what we have learned about this group after decades of study, to summarize gaps in the literature, and to reflect on how we may use the current state of knowledge to conserve these fascinating species. Initially intended as a focused review of the two most well-studied species in the genus *Gopherus*, *G. agassizii* (Mohave Desert Tortoise) and *G. polyphemus* (Gopher Tortoise), the book developed into a comprehensive treatment of the entire genus. The editors offer the work as a resource to professional biologists and agencies working with North American tortoises as well as a teaching aid, hobbyist's reference, and casual read for nature-lovers—although we presume that the former group is more likely to benefit than the latter. Although the book's size appears modest, the content delivers an in-depth look at the five recognized tortoise species.

The book comprises eighteen chapters. Although not formally structured in this manner, chapter topics fall within broad categories of evolution, physiology, and health (chapters 1–8), natural history and population ecology (chapters 9–16), and human dimensions and conservation (chapters 17–18). Authors represent numerous universities, state and federal agencies, and research organizations, and include many long-standing experts in this field of research. Within each chapter, authors address a particular topic for all five *Gopherus* species but vary in their approach and style. All chapters begin with a brief introduction of the topic and its relevance to tortoise biology. Then, authors review relevant concepts and data from published articles, white papers, conference proceedings, unpublished studies, and personal observations. While many chapters take stock of the current state of research, some chapters present new findings from novel data compilations and analyses (e.g., Chapter 12, Social Behaviors of North American Tortoises and Chapter 13, Nesting and Reproductive Output among North American Tortoises). Throughout the text, authors often compare traits across species, describe and compare techniques and experimental approaches, examine evidence for ecological theory within existing data, and suggest new avenues for research to advance our understanding of the genus. Illustrative materials include black-and-white photographs, diagrams, data plots and tables, and sample data sheets.

The editors and authors have succeeded in compiling an impressive collection of literature on a group that can be frustrating to study, as some data exist in hard-to-access sources or are entirely unpublished. This compilation, combined with the commentary on the current state of knowledge and identification of further avenues of research, make this text most useful to professionals working with this genus or with related species. Graduate students working with *Gopherus* should also take note: the book not only provides valuable background information about each species, but many chapters review common techniques used in tortoise research. Readers with a more casual interest in North American tortoises may find the *Gopherus* descriptions in "Turtles of the United States and Canada" (Ernst and Lovich 2009) more approachable; however, from Chapter 9 and onwards, this book becomes more accessible to those not already familiar with scientific terminology or specific sub-disciplines.

Many aspects of tortoise biology apply to numerous ecological systems, and interesting biological concepts throughout the book may appeal to a wider professional audience. The extant *Gopherus* species span varied habitats that relate to interesting evolutionary relationships, behavioral and physiological adaptations, and life history trade-offs. Certain chapters reflect the trial, error, and advances made over decades of management that may inform other managers facing similar challenges: the difficulties in documenting trends in cryptic or long-lived species (Chapter 14, Abundance of North American Tortoises), the application of population genetics to species management (Chapter 15, Population and Conservation Genetics of North American Tortoises), and the complexity of threats that deter species and habitat conservation (Chapter 18, Threats and Conservation Needs of North

American Tortoises).

The book presents some challenges, and improving a few key elements would have contributed to its overall cohesiveness and use. Some chapters are closely related and may have benefited from additional chapter structuring (similar to those suggested above), with section introductions tying the elements together. Without this structuring, the book begins abruptly and seems to assume some prior knowledge of *Gopherus*, diving headfirst into the genus with little context or placement in the higher taxa. This dynamic is apparent throughout the book, as chapters vary widely in the amount of background knowledge provided. At times, this variation can hinder how the information is conveyed.

While many chapters provide useful summary tables that efficiently review the breadth of information known about the tortoise species (e.g., review of home range data in Chapter 11), many chapters could be improved by effective use of figures and photographs. Generally, the plots and diagrams are clear and valuable visualizations of the text; however, in a few cases, figures are difficult to interpret or are ill-suited for black-and-white print. Similarly, the informative text of the book varies in its approachability. At times exhaustive lists of the literature available on a topic detract from the general message of the section. Authors clearly faced a trade-off—sacrifice clarity and interpretation of material for thorough lists of facts. Perhaps additional table presentations of references or data numbered within the text would allow sections to read more smoothly but still allow access to detailed information when needed.

Lastly, we believe there is disproportionate emphasis on the organismal biology of *Gopherus,* which comes at the expense of discussing their context within the larger ecosystem. For instance, ecological roles could be further explored. In particular, relationships between tortoises and other vertebrate species in the environment are noticeably lacking. This shortcoming is odd considering some tortoise species act as ecosystem engineers. Conservation issues and initiatives could also be described in more depth. There is little discussion about the unique problems captive tortoise populations pose to conservation or the relative success of management and conservation measures taken to ensure species persistence.

While this tome may not be as approachable to a wide audience as the editors desired it to be, it is a useful reference that many researchers and professionals will want to add to their book shelf. *The Biology and Conservation of North American Tortoises* gathers references and data from a variety of sources to summarize our knowledge of these long-lived reptiles. This mini-library of tortoise resources will benefit professionals and managers working with the genus and provide students with a crash course in tortoise research. The unique biology of North American tortoises presented in this text will no doubt inspire professionals to investigate broader theories within this system and promote conservation of our disappearing species.

Acknowledgments.—CMA wishes to disclose professional affiliation with several chapter authors within the U.S. Geological Survey. Her contributions to this review focused on the use of the book as a whole and chapters by unassociated authors.

PUBLICATIONS RECEIVED

Iconographie Générale des Ophidiens by Giorgio Jan and Ferdinando Sordelli, riedizione a cura di Stefano Scali. 2012.

Memorie della Società Italiana di Scienze Naturali e del Museo Civico di Storia Naturale di Milano (http://scienzenaturali.org/), Volume XXXVIII. 12 + [356] pp. Hardcover. €50,00 (approx. US $56.00 plus postage). ISSN 0376-2726.

This is a reprint edition of the classic snake work by Jan and Sordelli known simply as the *Iconographie.* Originally published between 1860 and 1881 it features 300 superb black-and-white plates including 8430 lithographic illustrations. The work was issued in 50 livraisons of six plates each, and attempted to depict all the snakes of the world then known, many for the first time. Most plates show the scalation of the anterior and posterior parts of the body in detail with smaller inset views of the head scales, body cross sections, and occasionally other features. The last five plates depict skulls in various views. The majority of plates illustrate numerous species, but Jan chose as his first plate one that shows only the striking *Erpeton tentaculum.* A colored version of this was used as a promotion for subscriptions to the work and in this edition it is reproduced on the dustjacket. The text of the *Iconographie* is limited to the contents pages, which list the species, their geographic origin and the identity of the collections that provided the specimens illustrated. The work was complemented by a number of monographic works by Jan (not reproduced in this edition), and more were planned but never published.

This edition, edited by Stefano Scali, herpetological curator of the Museo Civico di Storia Naturale di Milano, includes a brief bilingual (Italian/English) introduction of eight pages about Jan, the history of the collection, and the *Iconographie* itself. The introductory material also includes a brief history of the Milan Museum after Jan. Unfortunately, much of the collection was destroyed by incendiary bombs in 1943. The original *Iconographie* is one of the most valuable books in herpetology and even the previous facsimile of the work, published by J. Cramer, Wheldon and Wesley, and Hafner Publishing in 1961 has become uncommon and typically fetches many hundreds of dollars when copies become available. In this edition, published as a special issue of the memoires of the Milan Museum, the plates are reproduced at a slightly reduced size, but the fine details remain visible. The *Iconographie* remains an important work of both artistic and scientific achievement and now that it is once again available, should be on every herpetologist's shelf.

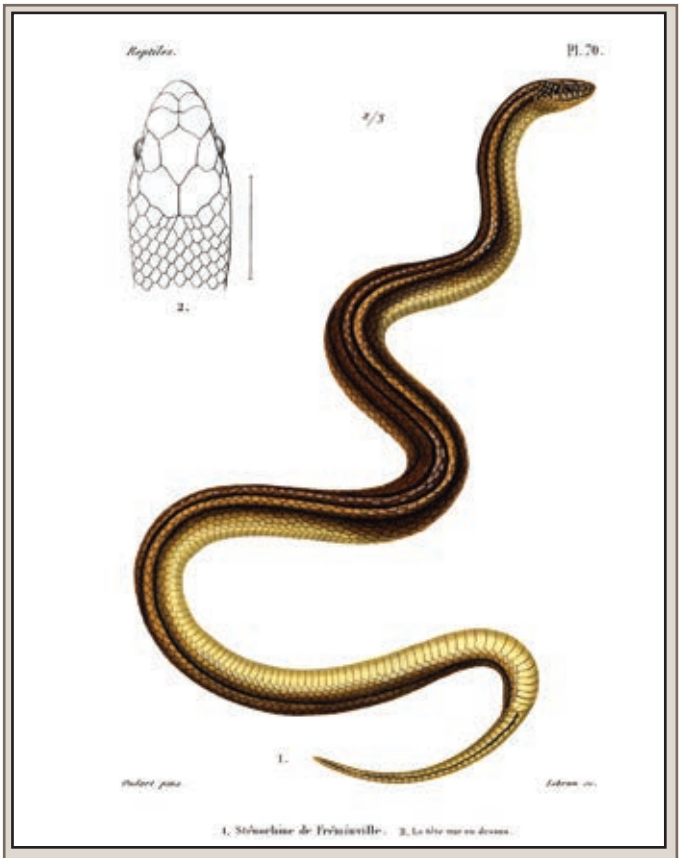
Identifying Amphibians and Reptiles in Zoos and Aquariums



PLUS ÇA CHANGE, PLUS C'EST LA MÊME CHOSE [THE MORE THINGS CHANGE, THE MORE THEY STAY THE SAME]

—*JEAN-BAPTISTE ALPHONSE KARR, 1849*

Reptiles and amphibians are relatively unique in the sense of constantly changing taxonomies. That phenomenon simply is not a big operative problem for bird and mammal zoo personnel. To gain a sense of why this is happening, refer to Frost and Hillis (1990). There is confusion caused by changes in both standard and scientific names in herpetology. The general principle in a zoo is that one wants to be talking about the same species when putting live animals together for breeding or exhibit or analyzing records for genealogy or research. During a visit to the Dallas Zoo when I was there, an academic colleague specializing in snake taxonomy and systematics was chiding me about using a supposed outdated technical name on our graphic panels. I suggested that he consult Hobart M. and Rosella B. Smith's *Synopsis of the Herpetofauna of Mexico, Vol.* III (1976) and look up the number of synonyms for the Slatey Gray Snake (*Stenorrhina freminvillei*). I said that we would have to keep a graphics designer on permanent contract just to deal with the continually fluctuating nomenclatural world. He called a week later, having counted the names, and said point taken. This incident provokes a broader question—what standard and scientific names should we use for amphibians and reptiles in our displays, records, and publications? This is not a trivial issue as virtually all of us can remember some of our colleagues fighting to near death over standard names, taxonomy, and systematics. Who can forget the tension between E. D. Cope and O. C. Marsh in the late 1860s (see Adler 2014)? Or the exchange between Pauly et al. (2009) and Frost et al. (2009)?

I was recently asked by a zoo worker what generic names should be used for some of the various North American ratsnakes: *Elaphe*, *Pantherophis*, *Pituophis*, *Mintonius*, or *Scotophis*, and whether some of these are now recognized as species or subspecies. All New World ratsnakes (and Old World representatives) are listed as *Elaphe* by Schulz (1996); the reason given for this conservative treatment is "…we are of the opinion that the genus *Elaphe* requires an overall revision... Such a revision could reveal aspects, which had been overlooked or not previously recognized, and lead to completely different conclusions." For instance, Collins and Taggart (2008) presented a new alternative generic name for the Eastern (*Mintonius gloydi*) and Western (*M. vulpinus*) Fox Snakes, now synonymized with *Pantherophis* by Crother et al. (2011) and Crother (2012). Corn Snakes and their allies were traditionally placed in the genus *Elaphe* but were recently referred to *Pantherophis* based on their close relationship to other lampropeltine colubrids of the New World (Burbrink and Lawson 2007). Different combinations are used by different authors and my colleagues are struggling with these differences; in other words, which names should they use? Some biologists believe that there is a rule that the most recent taxonomic paper should be the one used but there is no such established convention in the Code (*The International Code of Zoological Nomenclature*). Recently, a convincing description of the dangers of taxonomic vandalism leading to potential destabilization has appeared in the literature (Kaiser et al. 2013) and should be required reading for every zoo biologist. This paper clearly outlines acceptable methods for proper taxonomic and systematic research. Reject any approach that does not adhere to these principles.

COURTESY OF KRAIG ADLER AND TIM HERMAN

FIG. 1. Illustration of Slatey Gray Snake (*Stenorrhina freminvillei*) from *Erpétologie générale by* A. M. C. Duméril, G. Bibron, and A. Duméril, 1854 (plate 70 in Atlas). This species may hold the record for the sheer number of scientific name changes such as spelling errors since the original description as *Stenorhina Freminvillii* on p. 868. A reprint of this classic multi-volume work is available from SSAR.

I was discussing this potentially confusing issue with Roy McDiarmid from Smithsonian National Museum of Natural History and he recommended that the source for any nomenclatural decision used in any paper or any other purpose be stipulated. Roy, being the senior author of *Snake Species of the World* (1999), has had plenty of experience with conflicting names. He pointed out that there are names currently in use that he disagrees with and will not use, but that his readers need to know his reasoning for the decision. This approach makes sense to me so I am recommending here that the source for any name always be included in the beginning for all zoo animal records and placed in the permanent record for graphics panels (archived copies of the designs underlying all displays) and publications.

As a starting point, I use three sources for verification of current usage—*The Reptile Database* (Uetz and Hošek 2015, an online reference that is regularly upated), *Amphibian Species of the World* (Frost 1985 and its online successor, Frost 2015), and *Scientific and Standard English Names of Amphibians and Reptiles of North America North of Mexico, with Comments Regarding Confidence in Our Understanding* (Crother 2012). However, decisions also had to be made to produce these sources, and decisions sometimes are poorly justified. The SSAR checklist (Crother 2012) is perhaps better in providing more information about the sources of taxonomic usage and reasons for not following certain proposals. Registrars and others responsible for zoo animal records justifiably complain that different names (sometimes misspelled) are often submitted without explanation by curators and keepers to be used for an accession record, and new names sometimes suddenly appear in the daily animal records. While change is inevitable, in these situations retrieval of important data may be compromised. Zoo curators need to check records carefully for names used at their own zoo or elsewhere and take care to ensure that names are consistent or that synonymies are explained. When changes occur, this fact must be highlighted, with the source material, for the zoo's records and also for central databases such as ISIS and studbooks.

A good example of the challenges faced by curators and registrars who might not be trained in herpetology is the taxonomic history of North American ratsnakes (Fig. 2). In a controversial paper in which he applied the then-new Evolutionary Species Concept, Joseph T. Collins (1991) proposed elevating 55 geographically disjunct amphibian and reptile subspecies to species level, including the Fox Snake from *Elaphe vulpina gloydi* to *Elaphe gloydi,* without supporting evidence but simply because these subspecies were, as he wrote, "mapped as allopatric" in various publications and were "in some way morphologically (and presumably genetically) distinct." In the *Catalogue of American Amphibians and Reptiles*, both subspecies (*E. v. vulpina* and *E. v. gloydi*) were recognized (Powell 1990). In *Standard Common and Current Scientific Names for North American Amphibians, Turtles. Reptiles and Crocodilians (fifth edition)* published by The Center for North American Herpetology in 2002 by Collins and Taggart, both Fox Snake taxa are listed as species and the generic name *Elaphe* is used throughout. Although we were friends for many years, I never agreed with Collins about his instantaneous adoption of proposed name changes.

In the IUCN Red List of Threatened Species: "Although Burbrink concluded that the molecular data show that *E*[*laphe*] *alleghaniensis* and *E. spiloides* represent independently evolving units with separate evolutionary histories and thus should be recognized as different species under the evolutionary species concept, contact zones were not critically examined, so the nature and dimensions of clade boundaries, and the precise distributions of *alleghaniensis* and *spiloides* along the length of the Appalachians, remain uncertain. In view of the uncertainties and the need for further study, Burbrink's taxonomic revision has not been adopted in this database" (Hammerson 2007). In *The Reptile Database*, these taxa are listed as Eastern Ratsnake (*Pantherophis alleghaniensis*) and the Midland or Gray Ratsnake (*P. spiloides*). In Crother (2012), this statement justifying the committee's decision is offered: *P. obsoletus* (Say, 1823)—Western Ratsnake. "Based on the congruence of morphological (Burbrink, 2001, Herpetol. Monogr. 15:1–53) and mitochondrial data (Burbrink et al., 2000, Evolution 54: 2107–2118), Burbrink divided *P. obsoletus* into three species (*P. alleghaniensis, P. obsoletus* and *P. spiloides)* with no subspecies." In 2008, Collins and Taggart resurrected the genus *Scotophis* for Burbrink's three taxa, i.e., *S. alleghaniensis*, *S. spiloides*, and *S. obsoletus*, in response to the findings of Burbrink and Lawson (2007) but this has not been followed by subsequent workers (e.g., Pyron and Burbrink 2009). In 2014, Wallach et al. published *Snakes of the World*, a compendium that followed the arrangement of the SSAR checklist (Crother 2012). This classification is also followed by the NCBI (National Center for Biotechnology Information) taxonomy database but there is

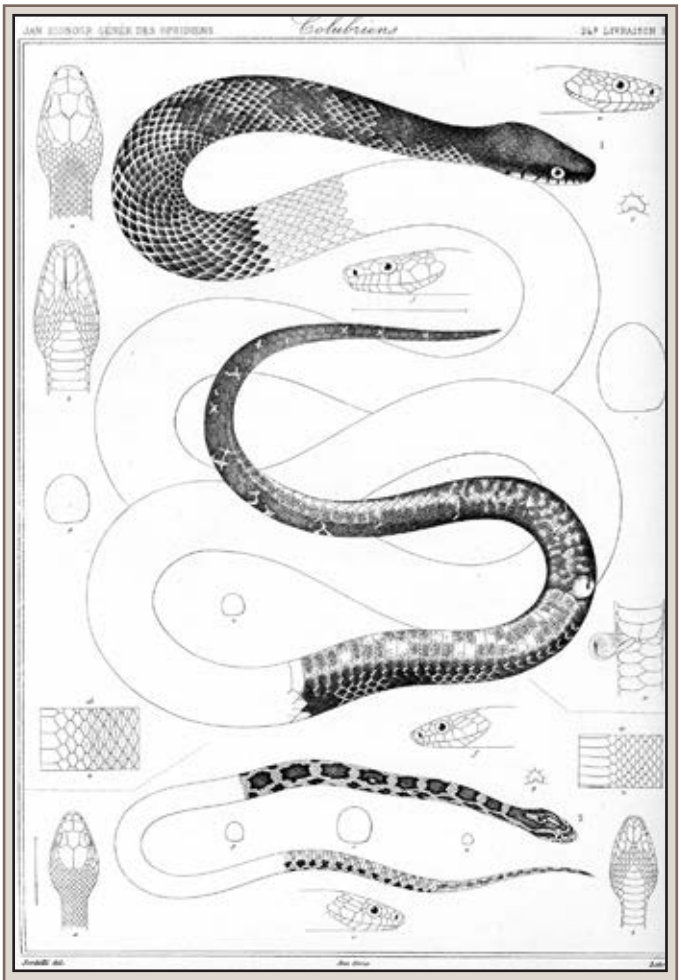

Fig. 2. Fair warning to ophiophobic tourists visiting Washington DC—Eastern Ratsnakes (*Pantherophis alleghaniensis*) are commonly found in the middle of the city at Smithsonian National Zoological Park. Illustration of *Elaphis alleghaniensis* from *Iconographie Générale des Ophidiens* by Georges Jan and Ferdinando Sordelli in 1860–66.

COURTESY OF RON GOELLNER, ST. LOUIS ZOO

FIG. 3. When the beautiful reptile building opened at the Saint Louis Zoo in 1927, R. Marlin Perkins was installed as curator and Moody J. R. Lentz was his assistant. During those early days, one popular feature was force-feeding large constrictors—such as "Blondie," the Reticulated Python shown here—every other week. Huge crowds attended the event as is evident in this undated photograph. Lentz (third from right) is holding the head. Note that a caulking gun is being used to squirt gruel into the snake's esophagus.

a disclaimer stating that this is not an authoritative source for nomenclature or classification. In ISIS (International Species Information System) /ZIMS (Zoological Information Management System), the administrators admit that they cannot keep up with taxonomic changes. As of this writing, it is current to 13 October 2014. Here are the entries: Ratsnake = *Elaphe obsoleta*; Black Ratsnake = *Elaphe obsoleta obsoleta.*

The term "ratsnakes" is currently used in an historical sense, inclusive of both Old and New World representatives that we now know are not closely related (Utiger et al. 2002). In the New World, the generic name *Bogertophis* has been used for the Baja California Ratsnake (*Bogertophis rosaliae*) and Trans-Pecos Ratsnake (*B. subocularis*) since 1988. The generic name *Senticolis* refers to the Green Ratsnake (*S. triaspis*) from SW USA, Mexico, and Central America. Both genera were recognized by Liner (1994) but not Schultz (1996). The Yellow-red Ratsnake or Yucatan Ratsnake, *Pseudelaphe flavirufa*, is found in Mexico and Central America. For most of its taxonomic life this species resided within *Elaphe*, but was transferred to *Pseudelaphe* by Utiger et al. (2002); the vast majority of published references, including Schultz (1996), list it under its older name.

Pet names are a different problem. My wife Judith Block, retired registrar at the National Zoo, once asked several keepers to help identify some primates in the collection: "When I took the gibbon records over to the Monkey House and asked which animal was named 'Spook,' three of them pointed to three different animals. It was also the primate keepers who taught me that an animal's name is very fluid. One macaque started off as 'Mary,' became 'Margie' then 'Mom' then 'Granny.' And all of the keeper staff contributed to my learning that often the formal name given in consultation with the Embassy or as the result of a contest is not what the animal is actually called—or even close. These experiences, along with many others, taught me not to rely on people's memory when creating and analyzing zoo records." I have argued before (Murphy and Card 1998) that for various reasons pet names should not be used in zoos but many of my colleagues disagree with me.

Knowing precisely which live animals are being assembled for breeding has always been critically important for zoos and aquariums. This has often been difficult because locality data for specimens or their ancestors is seldom known (and even if known rarely kept or at least easily retrieved) and DNA paternity/maternity analyses are virtually never conducted. And now, as these institutions focus on captive breeding colonies and conservation programs that might involve releases, precise identification is even more important (see Soulé and Kohm 1989). My overall impression is the importation of live animals from the field has diminished over the past several decades and the importation of biomaterials for research has increased.

Marking reptiles and amphibians for certain identification of individuals in the collection is an important component as well. Methods are described in several publications (Honegger 1979; Heyer et al. 1994, 2001; Ferner 2007; McDiarmid et al. 2012). Using PIT tags and photographs are helpful methods. At Dallas Zoo, we sometimes placed animals with distinct patterns and colors on a color copier to obtain a permanent record.

It is imperative to keep track of individuals, their origin, and genetic/breeding histories. This tracking may become even more complex when creating certain zoo animal colonies in the future. A recent paper by Cole et al. (2014) described a new species called Neaves' Whiptail Lizard (*Aspidoscelis neavesi*). Their abstract: "The first known tetraploid amniote that reproduces through parthenogenetic cloning by individual females is named and described. The species originated through hybridization between *Aspidoscelis exsanguis* (triploid parthenogen) x *Aspidoscelis inornata* (diploid bisexual or gonochoristic species) in the laboratory." It should be mentioned that not all herpetologists agree that a new species developed only in captivity represents a new taxon.

I may be too old to change but I simply cannot bring myself to use some new names even when a strong case is made to do so (see Reynolds et al. 2014). The Reticulated Python (*Python reticulatus*) was described by Fitzinger in 1826 but is now listed as *Malayopython reticulatus* in The Reptile Database. The Fitzinger name has been used for 170 years. At some point, I may be able to adapt to *Malayopython* but it will be challenging (Fig. 3).

It is easy to reject the generic name *Broghammerus* Hoser 2004 and the six Reticulated Python subspecies for the reasons enumerated by H. Kaiser and colleagues (Kaiser et al. 2013). Unfortunately, a number of zoos, governmental agencies and other institutions, and herpetoculturists have been using this generic name in their online and printed materials including promotional, care, and information sheets—the lack of scientific rigor and indifference to acceptable standards for naming animals will certainly cause confusion when lists of taxa are generated for conservation purposes and studies on herpetofaunal biology are undertaken. Several examples: Rawlings et al. (2008) refer to the Reticulated Python as *Broghammerus reticulatus* and subspecies *jampeanus* and *saputrai* (by implication). The U.S. Fish and Wildlife Service (USFWS) listed the Reticulated Python as *Broghammerus reticulatus* or *Python reticulatus* in several Federal Register documents dealing with possible injurious wildlife species. Reed and Rodda (2009) use *Broghammerus reticulatus* in the frontispiece, captions of their figures, and tables in the joint report by USFWS and U.S. Geological Survey (USGS) and recommended the following: "Rawlings and others (2008) opted for splitting, especially as a suitable name was already in use in

the literature for the Reticulated Python. Adherents of this point of view will wish to use the name *Broghammerus reticulatus*."

I recommend again to curators, registrars, and records keepers that in order to remain as accurate as possible and ensure that the conventions and usage for all names are understood over time by all future reviewers of these records, any changes should be documented. If there is inconsistency, then an explanation of how it was resolved must be placed in the records. Any new names advanced by the curators must have the source included; a copy of at least the title page and preferably the abstract of the relevant source information should be required. Copying the entire paper would be helpful. The curator's name and sources are then kept in the permanent records. (I note here that pdf files can sometimes be obtained on the internet through Google Scholar search engine). Lists of protected species—CITES and other international treaties, and local lists such as USFWS—must be consulted as well to guarantee consistency.

Other recommendations:

—To understand reasons for the sometimes-heated debates in herpetological taxonomy, read Vences et al. (2013) and Wüster and Bérnils (2011). These disagreements are unlikely to be resolved in the forseeable future.

—The IUCN Red List is a set of conservation statuses and recommendations. It is not to be used as a source of taxonomic information. It is updated too slowly and sporadically to be used as such.

—The online system AmphibiaWeb is linked to the IUCN list and provides information on amphibian declines, natural history, conservation, and taxonomy. There are differences between the taxonomies of AmphibiaWeb and *Amphibian Species of the World*. One helpful feature is as a source for photographs called "Photobrowser." The section called "Stories from the Field" is interesting reading highlighting the work of amphibian biologists.

—Follow *Amphibian Species of the World* and *The Reptile Database,* plus the SSAR Standard Names List for English names for US/Canadian taxa. *The Reptile Database* is not perfect, but clearly it is the best thing available. Specifically do NOT use field guides, Wikipedia, or any other taxonomy on the web (other than the above).

—Update taxonomies (across ALL zoo records and signage) once a year. This seems more efficient and likely to occur than rushing to the registrar every time a new taxonomic paper is published. Most curators have to file annual collection plans. Complete taxonomic review of the collection—and appropriately annotated changes to all zoo records—should be a mandatory part of this process.

—ISIS and AZA taxonomic lists are outdated to the point of non-functionality. In AZA guidelines, I believe that Frost (1985) is listed as the official taxonomy for zoos to follow for amphibians. By extension, its online descendent (Frost 2015) then is the official list for AZA.

—Read David L. Hull's book *Science as a Process: An Evolutionary Account of the Social and Conceptual Development of Science* (1988).

—Arrange to have an advisor apart from the zoo profession who can suggest proper taxonomies for the records.

—During my zoo career, there has been a reluctance by some zoo biologists to update taxonomies (sometimes for over a decade) for graphics, records, or other purposes, and budget constraints are usually given for one of the reasons. I remember visiting one US zoo with a large herpetological collection where the labels were typed on paper with a barely visible font size and were so old that they were yellowed and turning to dust—the curator said that visitors do not read signs anyway so why should he bother to produce more accurate and aesthetic versions? Another reason offered is that new names are too difficult to learn. When Arnold Kluge changed the generic name of the Green Tree Python from *Chondropython* to *Morelia* in 1993, there was an outcry from some in the herpetological community that was astonishing. Some of my colleagues refuse to use the latter name to this day and will tell anyone who will listen. These are unacceptable excuses for a profession claiming to have a scientific underpinning, especially in this digital world where searching for relevant publications is much easier.

—In summary, evaluate each proposal on its own merits, and also defer to species authorities in cases where you do not have enough knowledge. Clearly there are taxonomic changes that an informed reader can see that warrant immediate adoption given the breadth and depth of evidence (*Natrix* vs. *Nerodia* or *Elaphe* vs. *Pantherophis*), while other proposals, although put forth by experts, probably warrant an extended period of evaluation. Examples of *Lithobates* vs. *Rana*, or *Bufo* vs. *Anaxyrus* come to mind; in these cases there is general agreement on the evidence, but it comes down to whether one wants to carve up a monophyletic group, albeit a large one. In general, I would advocate a conservative approach, make changes when some degree of consensus in the herp community develops, and consult with one or more herpetologists with taxonomic expertise.

As an aside, Kraig Adler told me that as a brash new graduate student at the University of Michigan Museum of Zoology in 1962, he dashed into the office of prominent herpetologist Norman Hartweg waving a newly published paper that made wholesale nomenclatural changes in the Latin names of turtles and insisted that all the labels in the museum collection be changed. Professor Hartweg told this young chap to calm down as no changes were going to be made—the one certainty was that many new changes will prove to be in error and be rejected, and that the older names will return to former prominence. As, in fact, they were.

Acknowledgments.—This contribution is dedicated to René Honegger, Curator of Herpetology at Zürich Zoo in Switzerland between 1960 and 1999, now retired. He was responsible for many innovations in terrarium displays, captive husbandry and management, and national and international conservation issues. René compiled the first IUCN Red Data Book on reptiles (Part 1—Testudines, Crocodylia, Rhynchocephalia) in 1982.

I thank Smithsonian National Zoo registrars Judith Block and Mandy Murphy for reviewing an early draft. Kraig Adler, Kevin de Queiroz, Harry Greene, Robert Hansen, Roy McDiarmid, Joe Mendelson, and George Zug suggested ways to improve the paper. The staff of the herpetological department at National Zoo (Lauren Augustine, Matt Evans) were helpful as well.

The Taxonomic Status of the Snake Name *Tropidonotus roulei* Chabannaud, 1917

Paul Chabanaud was an ichthyologist associated with the Muséum National d'Histoire Naturelle (MNHN) in Paris, from 1915 to at least 1955. Although Chabanaud's primary research was with fish, 37 of his first 41 papers, published from 1915 to 1924, covered herpetological topics. During World War I he was tasked with identifying North African material that had accumulated from a variety of collecting expeditions during the previous decades (Dollfus 1960). From this material, as well as his own collections from West Africa, he named 17 taxa of snakes, only six of which are currently recognized.

One taxon named by Chabanaud (1917), *Tropidonotus roulei*, has managed to escape mention since its description. The description of *T. roulei* is of a juvenile specimen (based on the presence of the umbilical scar), said to have been collected on the "Nil Blanc, près Khartoum," i.e., on the White Nile, near Khartum, in central Sudan by Louis Vossion in 1882. Suggesting that it was related to the Eurasian Natricinae, Chabanaud assigned this new species to the then large genus *Tropidonotus* Kuhl, 1824, and more precisely to the genus "*Tropidonotus* (s. str.)," namely the subgenus *Tropidonotus* as defined by Boulenger (1893).

Because there are no natricines known from northeastern Africa, *T. roulei* could represent either a novel taxon, or could be assigned to an existing taxon with, therefore, erroneous locality data. An examination of the specimen (MNHN 1917.0154; Fig. 1), still in very good condition, proved the latter supposition to be correct—the specimen is a juvenile *Nerodia erythrogaster* (Forster, 1771)—a species of natricine that occurs only in eastern North America. The purported collector, Louis Vossion (1847–1906), was a French consul general who was assigned to numerous posts around the world, including Burma (1877–1880) and Sudan (1880–1882; Hill 1967). His only known stay in the United States was at Philadelphia during the early 1890s (Vossion 1897). The U.S. visit put him in proximity of *N. erythrogaster* populations on the Delmarva Peninsula. However, the holotype of *T. roulei* differs morphologically from Atlantic Coast specimens (see below), and is supposed to have been collected a decade earlier. The holotype is the only herpetological specimen collected by L. Vossion that was reported upon by Chabanaud, so there is no means to associate it with other material. The fact that the specimen was catalogued 35 years after its supposed capture permitted ample opportunity for accidental mixing of the holotype and any collection data with African specimens.

The holotype of *T. roulei* is described as follows (where different, Chabanaud's characters follow in parentheses): neonate; total length 305 mm; tail length 64 mm; nostrils lateral; eye large, equal to the nostril–orbital distance; internasals as wide as long; prefontals longer than wide (Chabanaud's figure shows wider than long); frontal twice as long as wide, with concave sides at suture with supraoculars; nostril lies between two nasals; loreal slightly taller than long; 1 preocular; 3 postoculars; 1 anterior and 3 middle temporals; 8 supralabials, the 4th and 5th bordering the orbit; 9 infralabials; anterior chin shields elongate, bordering first 5 infralabials; anterior chin shields longer than posterior pair (Chabanaud's figure shows them to be about equal in length); 25 dorsal scale rows at midbody, each with a keel; 148 ventrals; anal divided; 64 subcaudals, paired. The subcaudal scale count is within the range of females for *N. erythrogaster*, and lower than known counts for males. The 31 dorsal blotches are dark brown, the lateral bars darker brown, with the lateral interspaces pink tan. The ventral ground color is yellowed cream. The head is marked by fused, black-edged parietal spots, a pale post-parietal bar, and a dark postorbital band on each

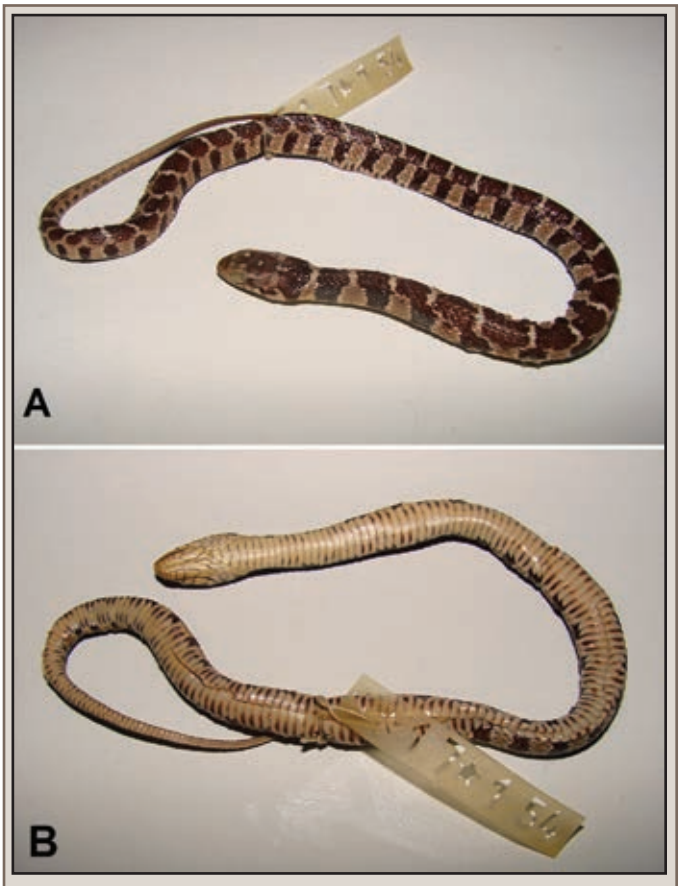

FIG. 1. Holotype of *Tropidonotus roulei*. A) dorsal view. B) ventral view.

side. All of the preceding characteristics are within the range of normal variation for *N. erythrogaster* (Conant 1949, 1969; McCranie 1990). After over 130 years in preservative the holotype surprisingly retains lifelike coloration. In living neonates the lateral ground color is brick red or reddish brown, the dorsal and lateral blotches and head markings are nearly black or brownish black, and the venter is dull yellow (Fig. 2).

Nerodia erythrogaster was once divided into six subspecies that were based on adult color pattern, with some correlated variation in juvenile color pattern (Conant 1949, 1969; McCranie 1990). However, Makowsky et al. (2010) showed that there was no genetic basis for taxonomic subdivisions, and considered *N. erythrogaster* to be a monotypic, wide-ranging species—an interpretation that was followed in Crother (2012). Although the blotched color pattern exhibited by the holotype of *T. roulei* is common to neonates of all of the former subspecies, we can try to specify to which of them the holotype of *Tropidonotus roulei* could be referred. In *N. e. alta* and *N. e. bogerti* the lateral bars are discretely shorter than those of the other former subspecies, and of the holotype of *T. roulei*. Also, those two morphs occur only in remote sites in the interior of northern Mexico, and were not discovered until the middle 1900s. Unlike the holotype of *T. roulei*, neonates of the former nominate race, of the Atlantic coastal and far eastern Gulf of Mexico drainages, possess a fairly uniform, dark cap that lacks the pale parietal and post-parietal marks, and the cap tends to be coalescent with the dark postorbital bands. Populations from the upper Midwest (subspecies *neglecta*) also lack the pale parietal markings, and usually have 23 midbody scale rows.

Fig. 2. *Nerodia erythrogaster*, neonate living specimen from USA: Louisiana: Baton Rouge. A) dorsal view. B) ventral view.

Other populations were previously assigned to the subspecies *N. e. flavigaster* and *N. e. transversa*, which occur in the south-central United States and northeastern Mexico. We are unaware of any character that will differentiate neonates of these populations, and the holotype of *T. roulei* resembles examples of both (JB, pers. obs.). Therefore, we cannot specify the possible origin of the holotype more proximal than the combined geographic ranges of the two morphs. Three nomina from that area, *Tropidonotus transversus* (Hallowell, 1852), *Nerodia woodhousii* (Baird and Girard, 1853), and *Nerodia couchii* (Kennicott, 1860), have nomenclatural priority over *T. roulei*, whereas *Natrix. e. flavigaster* (Conant, 1949) does not.

Using mtDNA sequence data, Makowsky et al. (2010) derived three primary clades in United States specimens of *N. erythrogaster*. The clades showed an approximate east–west arrangement that only partly followed that of the color-pattern morphs recognized as subspecies by Conant (1949). Their "Western" clade encompassed all of the range of *N. e. transversa,* and nearly all of *N. e. flavigaster*. Because the two subspecies are rendered taxonomically inseparable, we recommend fixing the type locality of *T. roulei* to within the range of the Makowsky et al. "Western clade." As a consequence, we here correct the type locality of *Tropidonotus roulei* Chabanaud, 1917 to a locality in central North America. Furthermore, in order to respect the stability of the systematics of this group, which will prevent *T. roulei* from having priority in the case any potential taxonomic rearrangements within populations of *N. erythrogaster*, we specify it as being "near the banks of the Arkansas [River]", i.e. the type locality of *Tropidonotus transversus* Hallowell, 1852. In so doing, *Tropidonotus roulei* becomes a subjective junior synonym of *Tropidonotus transversus*.

Acknowledgments.—Kenneth L. Williams brought the description of *T. roulei* to Van Wallach's and JB's attention. Wallach asked PD to check the identity of the holotype, who then conveyed to Wallach and JB that it was a specimen of *Nerodia,* and provided the photographs for Fig. 1. We thank Ken and Van for their work in the matter of *T. roulei*, both of whom declined to participate as coauthors. Lastly, JB thanks his son, John-Paul Boundy, for capturing the snake illustrated in Fig. 2.

ABOUT OUR COVER: *Crotalus cerberus*

In Greek mythology, "cerberus" is the three-headed dog of Hades that guards the gates to the dark kingdom. The Arizona Black Rattlesnake was first described, in somewhat fitting and ominous fashion, as *Crotalus lucifer* by Elliot Coues (1875. Synopsis of the reptiles and batrachians of Arizona; with critical and field notes, and an extensive synonymy. *In* G. M. Wheeler [ed.], Report upon Geographical and Geological Explorations and Surveys West of the One Hundredth Meridian. Volume V: Zoology, pp. 585–633. U.S. Government Printing Office, Washington, DC), with two type specimens originating in Arizona's San Francisco Mountains. For many years thereafter, the Arizona Black Rattlesnake was considered a subspecies in the large *Crotalus viridis* (sensu lato), or "Western Rattlesnake" complex, that was in itself centered in taxonomic debate. Ashton and de Queiroz (2001. Mol. Phylog. Evol. 21:176–189) recommended recognizing the Western Rattlesnake group as two species, *Crotalus viridis* (containing two subspecies) and *C. oreganus* (containing seven subspecies, including *cerberus*). However, Douglas et al. (2002. Phylogeography of the western rattlesnake (*Crotalus viridis*) complex, with emphasis on the Colorado Plateau. *In* G. W. Schuett, M. Hoggren, M. E. Douglas, and H. W. Greene [eds.], Biology of the Pitvipers, pp. 11–50. Eagle Mountain Publishing, Eagle Mountain, Utah) recommended elevating seven of the nine subspecies, including *cerberus*, to full species status. *Crotalus cerberus* is currently recognized as a full species (Crother et al. 2012. Squamata: Snakes. *In* B. I. Crother [ed.], Scientific and Standard English Names of Amphibians and Reptiles of North America North of Mexico, pp. 52–72. Society for the Study of Amphibians and Reptiles Herpetological Circular 39) and identified by Pook et al. (2000. Mol. Phylog. Evol. 15:269–282) and Douglas et al. (2002, *op. cit.*) as the most basal member of its clade.

Arguably, one of the more charismatic of the southwestern rattlesnakes, the Arizona Black Rattlesnake is a resident of various mountain ranges and habitat associated with the Mogollon Rim, a mountainous shelf that extends in a northwestern-southeastern direction across Arizona and southwestern New Mexico. The species is also known from the northernmost Madrean Sky Island ranges in Arizona's Pima, Graham, and Cochise counties. The Arizona Black Rattlesnake is considered a generalist predator, consuming lizards, small mammals, and birds (Lowe et al. 1986. The Venomous Reptiles of Arizona. Arizona Game and Fish Department, Phoenix, Arizona. 115 pp.; Loughran et al. 2012. Herpetol. Rev. 43:144–145). Although the species occurs in a variety of vegetation communities, from Sonoran Desertscrub at 900 m elevation up to Subalpine Conifer Forests at 3000 m, individuals often rely on dense cover provided by woody debris and riparian vegetation (Schofer 2007. Movements, Thermal Biology, Habitat Use, and Natural History of *Crotalus cerberus* in Northern Arizona. Master's thesis, Northern Arizona University, Flagstaff, Arizona; Nowak 2009. Ecology and Management of Venomous Reptilian Predators. Ph.D. Dissertation, Northern Arizona University, Flagstaff, Arizona).

The Arizona Black Rattlesnake is a moderately-sized species with adult females averaging 614.9 ± 77.6 mm SVL and adult males averaging 792.2 ± 94.5 mm SVL. Lowe et al. (1986, *op. cit.*) reported maximum size as approximately 1000 mm SVL. As neonates, Arizona Black Rattlesnakes are light gray with brownish to reddish botches on the dorsum and lateral fields. However, with age, the background color darkens, sometimes to a rich, velvet black, usually with one or two rows of white, yellow, or orange scales on the anterior and posterior edges of the mid-dorsal blotches, but not the lateral aspect. Variation in physical appearance can be quite remarkable among or within populations, and even within individuals. Unique among rattlesnakes and perhaps one of the most emblematic traits of Arizona Black Rattlesnakes is their ability to undergo physiological color change (sometimes referred to as metachrosis)—lightening their background color to a light ashen grey and exhibiting a neonatal-like pattern, and returning again to the darker state. These often-dynamic color changes can occur quite rapidly when individuals are captured or confined (physiological) (J. Servoss, pers. obs.), or on a slower time scale through stages of ecdysis (morphological) (J. Servoss, pers. obs.). Lowe et al. (1986, *op. cit.*) and Meachum (1999. Cold Blooded News 26[3]:1–9) suggest physiological color change may occur in response to diel patterns by lightening their background color at night; however, this is not consistently observed and thus might indicate greater individual control of the process.

Our cover image features a large adult male Arizona Black Rattlesnake, recorded by **Jeff Servoss** in the Sierra Ancha Mountains in Gila County, Arizona, using a tripod-mounted Canon PowerShot G6 with shutter speed set at 1/60, f/8, and using a Canon Speedlite 420 EX in compulsory mode for fill-flash. Jeff is a Wildlife Biologist with the U.S. Fish and Wildlife Service in Tucson, Arizona, working predominantly on species status evaluations and conservation and recovery planning and project implementation for reptiles and amphibians in the southwestern United States. His focus most recently has included the Sonoran Desert Tortoise (*Gopherus morafkai*), and federally threatened species including the Northern Mexican Gartersnake (*Thamnophis eques megalops*), Narrow-headed Gartersnake (*Thamnophis rufipunctatus*), and Chiricahua Leopard Frog (*Lithobates chiricahuensis*).

SSAR BUSINESS

Dean E. Metter Memorial Award for 2015

The Metter Memorial Award winner this year is Carmen Harjoe, a student in the Department of Integrative Biology at Oregon State University. She is a PhD student who is studying the population status of Western Toads, *Anaxyrus boreas*, in southeastern Alaska. Her major professor is Andrew Blaustein. Carmen's undergraduate work was in Fisheries and Wildlife with a minor in Biology at the University of Missouri—Columbia where Metter taught herpetology and other life sciences courses for over 30 years. She took herpetology there from Carl Gerhardt and Richard Daniel and did research in Carl's laboratory.

The Metter Award Committee extends its sincere thanks to all the students who submitted proposals this year. We wish all of you the best and look forward to reading about the results of your graduate work in the herpetological literature.

NEWSNOTES

Landers Student Research Award

The J. Larry Landers Student Research Award is a Gopher Tortoise Council competitive grant program for undergraduate and graduate students. Proposals can address research concerning Gopher Tortoise biology or other relevant aspects of upland habitat conservation and management in the southeastern USA. The amount of the award is variable but has averaged approximately US $1,000 per recipient over the last few years.

The proposal should be limited to four pages and include a description of the project, a budget, and a brief résumé of the applicant. This is an excellent opportunity for students to access funding for their project. Awards are typically recognized at the annual meeting to the Gopher Tortoise Council. Deadline for the application is 15 September 2015. Electronic submission is preferred. Please submit proposals to Bob Herrington (e-mail: bob.herrington@gsw.edu).

Haskell Award 2015

PHOTO BY DIRK STEVENSON

The Alison Haskell Award for Excellence in Herpetofaunal Conservation is presented by Partners in Amphibian and Reptile Conservation (PARC), in memory of Alison Haskell (1956–2006). This award is intended to recognize an individual from North America who exemplifies extraordinary commitment to herpetofaunal conservation, has thus far been an unsung hero, and has shown exemplary commitment to building or strengthening partnerships. Alison was one such person.

We are proud to announce the 2015 recipient of the Alison Haskell Award is **John Jensen.** John is currently the state Herpetologist for the Georgia Department of Natural Resources. John has directly contributed to the conservation of imperiled amphibians and reptiles, in particular Gopher Frogs and Eastern Indigo Snakes, through many successful partnerships. His efforts have also helped protect Georgia's freshwater turtles and rattlesnakes. His commitment and dedication to herpetofaunal conservation, in Georgia and beyond, is widely recognized among his peers. Additional information about John's efforts and achievements can be found on PARC's Alison Haskell Award Winners page (www. Please read more about John's efforts and achievements on PARC's Alison Haskell Award Winners page. (www.parcplace.org/). SSAR congratulation John on this well-deserved recognition.

The 8th World Congress of Herpetology (WCH8) Call for Symposia

The 8th World Congress of Herpetology (WCH8) will be held 15-21 August 2016 in Hangzhou, China. The Organizing Committee is currently inviting proposals for symposia at WCH8. Each symposium will last two hours, with eight 15-min presentations. If you are interested in organizing a symposium, please submit your proposal via e-mail no later than 31 July 2015 to the following addresses:

xiangji150@hotmail.com / jixiang@njnu.edu.cn (Professor Xiang Ji, Nanjing Normal University) and njlihong@outlook.com / njlihong@163.com (Dr. Hong Li, Nanjing Normal University).

The proposal should include:
1) The title of the proposed symposium
2) Names of the organizers and their affiliations
3) A brief description of the theme
4) A tentative list of speakers

All proposals will be evaluated by the Scientific Program Committee chaired by Professor Ya-Ping Zhang, and up to 30 will be selected based on scientific merit and the timeliness of the topic. The selected symposia will be announced by 31 August 2015.

For more information about the 2016 congress (WCH8), please visit the website at:
http://www.wch2016hangzhou.com

Nanjing Normal University, China

MEETINGS

Meeting announcement information should be sent directly to the Editor (herpreview@gmail.com) well in advance of the event. We also welcome brief reports of meetings; please consult the Editor for details.

15–19 July 2015—American Society of Ichthyologists and Herpetologists and The Herpetologists' League annual meeting, Reno, Nevada, USA. Information: www.asih.org

27–29 July 2015—World Conference on Monitor Lizards, Bangkok, Thailand. Information: monitor.conference.2015@gmail.com.

30 July–3 August 2015—58th Annual Meeting of the Society for the Study of Amphibians and Reptiles (with Partners in Amphibian and Reptile Conservation, Kansas Herpetological Society, and International Society for the History and Bibliography of Herpetology), Lawrence, Kansas, USA. Information: www.SSAR2015.ku.edu

6–9 August 2015—13th Annual Symposium on the Conservation and Biology of Tortoises and Freshwater Turtles, Tucson, Arizona, USA. Information: http://www.turtlesurvival.org/

18–20 August 2015—Northeast Partners in Amphibian and Reptile Conservation (NEPARC) annual meeting, Greenwich, Rhode Island, USA. Information: http://northeastparc.org/next-meeting-info/

16-20 September 2015—51st Annual Meeting of the German Society for Herpetology and Herpetoculture, Lyss, Switzerland. Information: www.dght.de

25–30 September 2015—18th World Congress of the International Society on Toxinology, Oxford, UK. Information: http://lpmhealthcare.com/ist2015/

6–8 November 2015—42nd Annual Meeting of the Kansas Herpetological Society, Hays, Kansas, USA. Information: http://www.cnah.org/khs/meetings.aspx

15–21 August 2016—8th World Congress of Herpetology, Hangzhou, China. Information: http://www.wch2016hangzhou.com/

John M. Legler 1930–2014: The Old Curmudgeon, the Turtle Biologist's Turtle Man of All Times

John Marshall Legler passed away on 28 March 2014 in Salt Lake City, Utah, of natural causes. He was born on 9 September 1930 in Minneapolis, Minnesota, to Fredrick William Legler and Helen Hertig Legler. He is preceded in death by his daughter Allison K. Legler (1985), and his wife, Avis Johnson Legler (2009), whom he married upon their graduation from Gustavus Adolphus College in St. Peter, Minnesota, in 1952 (Fig. 1). He is survived by their children: Austin F. Legler of Pambula, Australia; Edward P. Legler of Denton Texas; and Gretchen T. Legler of Jay, Maine. Avis was an artist, she cooked and raised the family, and often accompanied John with the children on field trips to Mexico and Central America; Austin learned to tell time and catch turtles at the same time while in the field in Mexico (Fig. 2). The family spent the better part of several years collecting turtles in Australia. He was an educator, a scientist, and a conservationist. He was an Olympic swimmer with four trophies and dozens of medals hanging in his office. Up until the last months of his life he swam daily. His turtle studies in Australia were based on the turtles he collected by diving in clearwater streams. He also painted gourds and built his own straw-bale building at his ranch in the mountains of Montana near a trout stream. I once made a faux paux, asking him when he was going to his cottage, he gruffly responded that "people in the East had cottages, Western men had cabins!"

AVANT GARDE STUDIOS

FIG. 1. John Legler, 1953, a year after completing his undergraduate degree.

John's family settled in Minneapolis, Minnesota after World War I. Their home had three lots with a huge rock pile in the back where his father kept free-roaming non-venomous snakes, and would feed them there. John and his brother used to catch sparrows and take them to the library to give to the snake lady, Grace Wiley, who kept poisonous snake; later she died from getting bitten by a cobra she was posing for a magazine photographer in 1948. John's father always told the boys not to take chances with venomous snakes. John had a whole family of descented skunks as pets; the young

used to follow the mother around. One of the young skunks was not descented completely, but that was ok; that was part of the mystique for people from Dusseldorf coming to live in the Wild Wild West of America, where you were free to do anything, including possessing wild skunks!

John began his academic life at a small liberal arts school in Minnesota. He did not have a raving interest, or even a passing interest for that matter, in turtles until he read Archie Carr's book on the turtles of North America. In going through John's files after his passing, I found a letter to Archie Carr with accolades about the *Handbook of Turtles* and how the book had stimulated John's interest in turtles and requested information about going to graduate school at the University of Florida under the tutelage of Dr. Carr. Carr never responded, only a graduate school secretary who sent him the application forms and stated that Dr. Carr would be in touch with John at a later date; no letter from Carr was found in the files. Imagine how turtle biology might have taken a different course had Legler worked with Carr! Maybe sea turtle conservation would have been more about the biology of the animals had Legler become involved.

He attended graduate school at the University of Kansas and was mentored by E. Raymond Hall, Edward Taylor, and Henry Fitch, despite the fact that those three were not on good terms with one another. Hall had a very stereotyped and eccentric behavior—entering and leaving the museum with a flare, and the same way each day, entering with a flourish and pirouetted bounding up the spiral staircase, and leaving by an old freight elevator, by grabbing a pole and doing a pirouette into it. One night, someone had overridden the safety on the door which prevented the door from opening if the elevator was not there; Hall lived through the fall. At another time Hall flew his body into a low table that was strategically placed in his path, where he entered his customary room with a flourish and greeted his groin with the edge of the table; Legler was positive this was set up by Taylor.

Legler earned his Ph.D. in anatomy and zoology (1959) and served as the Curator of Herpetology at the KU Museum of Natural History from 1955–1959. In 1959 he began teaching at the University of Utah as an assistant professor, achieving full professor status in 1969. In Utah, he developed the undergraduate program in human anatomy, earned the University's Distinguished Teaching Award in 1967, established the Legler Professorship and Chair of Anatomy, and retired in 1997 as Emeritus Professor.

Legler's 82 scientific publications were overwhelmingly focused on turtles, but also included papers on frogs and snakes. He regarded the critically acclaimed book on Mexican turtles (coauthored with Richard C. Vogt, 2013) as his major academic accomplishment. Two other publications have become classics in the turtle world: his PhD thesis (Natural History of the Ornate Box Turtle, *Terrapene ornata ornata* Agassiz [Legler 1960]; and The Life History of a Neotropical Slider Turtle, *Pseudemys scripta* (Schoepff), in Panama (Moll and Legler 1971).

Legler described or co-described new species of tortoises and freshwater turtles on three continents—*Gopherus flavimarginatus* from Mexico, *Kinosternon angustipons* from Panama, *Trachemys scripta taylori* and *Trionyx ater* (now *Apalone spinifera atra*) from Cuatro Cienegas, Coahuila, Mexico, a new genus and species of Australian chelid, *Rheodytes leukops,* as well as other species of Australian turtles. In addition, he described a snake, *Geophis aquilonaris* (now regarded as a subspecies of *G. dugesii*), and the Central American frog *Ptychohyla legleri* was named in his honor.

His main contributions to turtle conservation were the techniques he developed which saved the unnecessary slaughter of countless numbers of turtles to obtain stomach contents for dietary studies and eggs for incubation studies. With his son Austin, he developed a technique while in Australia to flush out stomach contents of turtles without causing life-threatening damage to the turtle (Legler 1977). John and Mike Ewert developed the technique of inducing oviposition in gravid turtles by the injection of 10 units of oxytocin per kg of body weight (Ewert and Legler 1978).

Legler formed strong, and sometimes colorful opinions of other turtle biologists. He regarded Gerald Kuchling as perhaps the most dedicated and brilliant turtle biologist working in Australia. He worked with Mike Ewert in developing the oxytocin technique, and found him to have interesting ideas but quite paranoid about others stealing his data.

A group of well-regarded scientists received their PhD under his guidance at the University of Utah: Jim Berry, Jim Bull, Jim Christiansen, Ed Moll, and Bob Winokur. Postdocs included Dennis Bramble, Eric Charnov, and Rick Shine. A festschrift in his honor was held at the 2010 JMIH meetings in Minneapolis, Minnesota, his home town; all but one of his former students participated.

After our Mexican turtle book was finished, John was at a loss for what to do with his free time and wanted to start on another book. He wanted to do South American turtles with me, but I insisted he do his Australian book and enlist Sean Doody to help him. They were working on the book when John died.

In 2008, John delivered a plenary talk at the 6th World Congress of Herpetology in Manaus, Brazil regarding his views on the most important aspects of turtle biology yet to be studied (Fig. 3). He delivered the keynote address at the Turtle Survival Alliance meeting at St. Louis in 2013, and with a twinkle in his eye showed us a unique and undescribed gland in the esophagus of a chelid turtle.

I first met John at the Turtle Ecology Symposium at the ASIH meeting in Williamsburg, Virginia in 1975. We remained close friends and colleagues over the next 38 years. With his passing, I've lost my best friend and life advisor. He is sorely missed, but his critical eye and perseverance for the finest science possible will always be with me.

Epilogue.—I interviewed John Legler in Salt Lake City on 23 March 2010. Parts of that interview have been incorporated in this obituary. Post-mortem I inherited John's academic life—his library, photographs, serial histological sections of the heads of 46 species of hatchling turtles, dried and stained turtle lungs, archives of published and unpublished data, unfinished papers and books, correspondence files, and his daily journal. I went through all the files and boxed it all up to be shipped to Brazil—93 boxes including six 4-drawer file cabinets, and 43 wooden cases for turtle skeletons.

CURRENT RESEARCH

The purpose of Current Research is to present brief summaries and citations for selected papers from journals other than those published by the American Society of Ichthyologists and Herpetologists, The Herpetologists' League, and the Society for the Study of Amphibians and Reptiles. Limited space prohibits comprehensive coverage of the literature, but an effort will be made to cover a variety of taxa and topics. To ensure that the coverage is as broad and current as possible, authors are invited to send reprints to the Current Research section editors, Ben Lowe or Chava Weitzman; e-mail addresses may be found on the inside front cover.

The Plight of Mitigation-Driven Translocations

Translocations to mitigate animal deaths due to human expansion (mitigation-driven translocation) is an often used, but poorly studied, tool to conform with laws regarding the conservation of species. For any one project, millions of dollars may be spent to relocate thousands of animals. For example, translocations of Mojave Desert Tortoises (*Gopherus agassizii*) for a single solar project could amount to US $22 million. In 2011, approximately 500 permits were issued in Florida alone for translocation of the Gopher Tortoise (*G. polyphemus*). Additionally, more money may go toward mitigation-driven translocations than conservation-driven translocations, which aim to supplement or reestablish populations. In the last 15 years, over AU $14 million has been spent on mitigation-driven translocations of the Green and Golden Bell Frog (*Litoria aurea*) in Australia, while less than a quarter of that amount has been spent on conservation-driven translocations of all other Australian amphibian species combined. Techniques used in conservation-driven translocations are scrutinized through experimental research published in peer-reviewed journals, and though mitigation-driven translocations stem from different motives, the authors argue that these translocations should undergo the same academic scrutiny as translocations for conservation needs. Without further investigation into the success of such mitigation-driven translocations, the authors question whether these animals are "being spared a socially unacceptable death via bulldozer only to perish out of view at a release site." Proper implementation and documentation would not only expose success rates, but could allow for an opportunity to test hypotheses and optimize methods based on empirical evidence. Due to the supply-driven nature of these translocations, the proportion of the population actually collected, along with the effects of these translocations on the local population into which the individuals were translocated, are frequently unknown. As such, and with the implementation of poorly executed techniques, it is likely that survival and establishment are low, and the assumed success rates may often be misguided. The authors urge for the investigation into the success of mitigation-driven translocations to become a responsibility of the developers, consultants, and regulatory agencies.

Sampling Site an Important Factor in Effects from Parasites and Pesticides

A variety of dynamics might influence the interactions between amphibians, parasites, and pesticides. Although pesticides may weaken vertebrate immune systems, they might also negatively influence the success of parasites. The fragmentation of wetland habitats might reduce transmission of parasites, similar to island effects on the composition of host and parasite

populations and assemblages. An additional conflicting factor might be host body size, as larger hosts might be exposed to higher amounts of pathogens, but might also represent relatively healthy individuals. Studies of Northern Leopard Frog (*Lithobates pipiens*) populations in agricultural and undisturbed wetlands in southern Quebec, Canada, have detected differences in leukocyte profiles and parasitic nematode prevalence and abundance. Here, the authors aim to explain these differing leukocyte profiles by testing for associations with nematode presence, pesticide levels, frog metrics and sex, and positive or negative association between pairs of nematode species. From five wetlands, the authors analyzed 82 blood smears and parasites from 146 frogs. These wetlands were sufficiently far apart to exceed known juvenile Northern Leopard Frog movements. Data were collected from juvenile frogs, ensuring interactions solely with natal environments. Neutrophil:lymphocyte ratios were used to measure potential response to stressors from both parasites and pesticides. Parasites were found in 82% of the frogs examined, with species richness ranging from one (33%) to four (2%), and significant interannual variability was detected when comparing these 2006 nematode abundance results with a 2001 study. While many patterns arose among frog metrics, leukocyte metrics, pesticide levels, and nematode richness and abundance, most of these correlations broke down when analyzing within-wetland patterns in place of pooling the frog sampling sites. These analyses revealed there are likely population differences both in metamorph size and nematode exposure or transmission. In general, pesticides likely did not affect nematode levels in these sites, but rather there is likely a combination of environmental variables impacting nematode abundance at sites with high parasite levels. This study also found lower stress indices in frogs exposed to higher herbicide levels, disagreeing with previous studies, and possibly associated with other variables in the frog populations. The authors stress the importance of incorporating sampling location as a variable in larger, comparative studies. This study illustrates the influence of spatial scale on host-parasite relationships, which is an important consideration as landscape ecology scales are increasingly employed by parasitologists.

The European Newt Arrives in Australia

Australia provides habitat for over 200 native frog species, but there are no known species of salamander or caecilian native to the country. Here, the authors document the invasion and establishment of the European Newt, *Lissotriton vulgaris*, near Melbourne, Australia. Of the seven sites surveyed in 2013 in the Melbourne area, *L. vulgaris* was detected in six, with a total male-to-female ratio of ~2.5:1. Through comparing sequences of two mitochondrial genes from wild-caught *L. vulgaris* in Australia with sequences available on GenBank, the newt was placed in the L2 haplotype group of the *L. v. vulgaris* subspecies, which has been identified in Germany, the Czech Republic, Slovakia, and Hungary. The authors used the software CLIMATE to compare precipitation and temperature variables between the species' native distribution and Australia to estimate the potential distribution in this new habitat. When using distribution of *L. vulgaris*, the authors predict suitable habitat in large portions of New South Wales, Victoria, eastern Tasmania, southern South Australia, and southwestern Western Australia. Much of the potential habitat in South Australia and Western Australia degrades in quality for these newts if only the subspecies *L. v. vulgaris* distribution is included in the model. As the climatic niche of a species might not necessarily be conserved in its invaded range, the authors advocate caution when considering these range predictions. Another important factor to consider is that the invaded area is denser with artificial water sources than the water available in the native range, possibly enabling higher levels of mobility in Australia. It is currently unknown how the establishment of this species could impact Australian biodiversity. They may pose a competitive threat to frog and invertebrate species, due to a similar trophic niche. Additionally, *L. vulgaris* may contain low levels of tetrodotoxin, a neurotoxin present in some species of Salamandridae. As this is the first recorded establishment of a caudate in Australia, the effects of this toxin on naïve predators is not known. To help determine the extent of possible effects of *L. vulgaris* on native species in Australia, the authors urge that the next step and top priority be to delimit the current extent of the species' Australian range.

Evidence of *Bd* in Illinois for >125 Years

Although disease caused by *Batrachochytrium dendrobatidis* (*Bd*) has caused die-offs in amphibian populations around the world, no population declines in the eastern or midwestern U.S. have been attributed to chytridiomycosis. Little is known of the evolutionary history of this fungal pathogen, and the origin of *Bd* in the U.S. could have deep historical roots, or could include invasive strains more recently introduced. The authors' objectives here were twofold: to use museum specimens to find the oldest evidence of *Bd* in Illinois, and to determine frequency of infection among species and areas across time. They investigated frog specimens representing 10 species across the state of Illinois and the years 1888–1989. The genera represented included *Acris, Anaxyrus, Hyla, Lithobates*, and *Pseudacris*. *Bd* prevalence was tested using established quantitative PCR assay protocols. Among these samples, prevalence of *Bd* was 13.2%, but *Bd* prevalence varied among species and decade. Specimens of *Lithobates sphenocephala* had the highest prevalence of *Bd*. This pathogen was also detected in *L. pipiens*, *Hyla chrysoscelis*/*versicolor*, and *Acris blanchardi*, while *Bd* was not found in the remaining six species. Prevalence of *Bd* was highest in the 1940s when comparing all frog species, but also within the subset of samples representing *L. sphenocephala*. This increase in prevalence in the 1940s may indicate an epizootic, though more and even sampling among species and years would be necessary to confirm.

From these samples, the earliest incidence of *Bd* detected in southern Illinois was in 1900, in 1888 in central Illinois, and 1892 in northern Illinois. One individual *L. sphenocephala* from 1888 with *Bd* represents the oldest reported record of this pathogen, followed by a Brazilian frog specimen from 1894. These results indicate a historic presence of *Bd* in Illinois, either because it was introduced before 1888, or because it is a native pathogen with deep evolutionary roots in the region. Though the role of *Bd* in past population declines is unclear, its presence suggests a possible explanation of historical declines in some species. As there is no evidence of population declines in *L. sphenocephala*, the high prevalence of *Bd* both presently and historically in this species raises the question of this species' role in *Bd* distributions and dynamics. The authors suggest future studies investigating the evolutionary history of *Bd* should include samples from the midwestern U.S. to evaluate whether this region is a point of origin for this now-widespread pathogen. Importantly, the authors have shed light on the historical prevalence of disease in the midwestern U.S., and documented the earliest known case of *Bd* in a *L. sphenocephala* specimen from central Illinois.

Denser Lizard Populations Promote Cannibalism in Adult Males

Insular species frequently evolve characteristics that differ from those of their mainland counterparts, due to decreased predation stress, increased population density, and thus increased intraspecific competition. These can include physiological, ecological, and behavioral changes. Behaviorally, high intraspecific competition may lead to an increased incidence of cannibalism and intraspecific aggression. Here, the authors examine the incidence of cannibalism and intraspecific aggression in two populations of Skyros Wall Lizards (*Podarcis gaigeae*) on the main island of Skyros and the satellite islet of Diavates. The wall lizards on Diavates have no interspecific competitors, nor predators, and individuals grow to much larger sizes than those on Skyros. The authors used staged encounter trials to identify frequency and latency of four aggressive behaviors: approach, run, attack, and capture. They hypothesized that males would be more frequently aggressive toward juveniles than females, lizards from Diavates would attack juveniles more frequently than those from Skyros, and adults from Diavates would be more aggressive toward age-peers than adults from Skyros. The trials determined that significantly more males from Diavates performed aggressive behaviors than males from Skyros, and of those that captured the juveniles, the males from Diavates did so in less time. While the proportion of males performing aggressive behaviors toward age-peers did not differ between the two locations, a higher proportion of males from Diavates performed the most aggressive behaviors of attacking or capturing toward age-peers. Few females performed any aggressive behaviors toward either juveniles or age-peers, and there were no significant differences found between female behaviors from Diavates and Skyros. As such, the frequency of aggression was significantly higher in males than females. All three hypotheses were supported in these experiments. While limited food resources has been described as a trigger for increased cannibalism, the Diavates population of wall lizards has an abundant food supply. In these wall lizards, the differences found between aggression levels may reflect increased competition and frequency of interactions between males for territory defense and mate control in a denser population on Diavates than those found on other islands.

Cooper, W. E., Jr., I. Dimopoulos, and P. Pafilis. 2015. Sex, age, and population density affect aggressive behaviors in island lizards promoting cannibalism. Ethology 121:260–269.

Are Pythons the Cause of Mammal Declines in the Everglades?

Everglades National Park (ENP) in South Florida has experienced declines in mammal populations coinciding with the invasion of Burmese Pythons (*Python molurus bivittatus*), yet whether the Burmese Python has caused these declines is a source of contention. Here, the authors test whether pythons drive the declines of Marsh Rabbits (*Sylvilagus palustris*) in ENP. The mortality risk from different causative agents was compared between rabbits in areas with and without established python populations. Marsh rabbits were collected from donor populations and assigned to one of three sites: a procedural control site in the Greater Everglades Ecosystem (GEE) with no pythons, and two sites in ENP. An additional control site, with few or no pythons, within ENP was also used but not manipulated. Mortalities were classified as a predation from a mammal, bird, non-python reptile, python, or unknown endotherm. A Cox proportional hazards model was used to estimate mortality risks from the various predators. Because pythons are ectotherms, the authors predicted that python predation would vary with environmental conditions, depending on temperature and water depth. A total of 68 rabbit mortalities were documented, 55 of which were attributed to a specific predator type. The rabbits released in ENP had a higher cumulative hazard risk from pythons, which accounted for 77% of their mortalities. In the control sites, however, 71% of the mortalities were due to mammals, and the only snake predation events in the control sites were by native rattlesnakes. Predation events by pythons in ENP were temporally heterogeneous, with higher rates of mortality with increasing temperatures, but water level did not influence predation events by pythons. Alternatively, the mortality events by mammals were not influenced by environmental changes. The lack of predation events by mammals in ENP may be attributed to effects of pythons on other mammalian populations. These data support the claim that Burmese Pythons are the likely cause of population declines in mammalian species in ENP, especially as the study system chosen in this experiment is generally resilient to predation pressure. In order to restore the health of Everglades National Park, mammal populations need to be recovered, and the population of these invasive pythons needs to be reduced.

Changes in the Commercial Reptile Trade: 1996–2012

The exotic pet trade is fueled by biodiversity-rich countries, and the conservation implications of taking wildlife from these regions is poorly understood. Using CITES Appendix II import data from 1996–2012, the authors address questions regarding the changes in the trade of captive-bred, ranched, and wild-sourced animals, and possible consequences of these dynamics for the sustainability of the live reptile trade. Though these data analyzed only represent animals legally traded between countries, CITES data is the only comprehensive global dataset of its type, and is thus a valuable resource. Over 18.8 million live reptiles on CITES Appendix II were imported for commercial purposes globally between 1996 and 2012. With peaks in 1996 and 2001, annual Appendix II reptile imports have decreased during this time frame, with a 32.8% decrease from 2001 to 2012, though the number of different species traded increased from 1996 to 2012. The Green Iguana (*Iguana iguana*) was consistently imported with the highest frequency, and Royal or Ball Python (*Python regius*) with the second highest frequency, and the top ten imported species accounted for over 75% of all trade. From 2001 to 2012, imports of wild-caught reptiles decreased by 71%, while imports of ranched reptiles increased by 4740%. The trade of *I. iguana* drove the decrease in captive-bred reptiles from 2001 to 2012, and excluding this species, the import of captive-bred reptiles increased by 202% between these years. Between 1996 and 2012, the proportion of ranched and captive-bred imports increased, while wild-caught imports decreased. Additionally, the proportion of reptiles from countries in their natural ranges decreased. The three regions exporting the most reptiles were Mesoamerica, sub-Saharan Africa, and South America, while the United States accounted for over half of all imports. The overall decline in the commercial trade of live reptiles could be a consequence of many factors, including an increase of in-country captive breeding, reduced demand, or increased legislative controls. The authors argue that the shift away from wild-caught reptiles and importing species from their native range could jeopardize incentive-based conservation. As the exporting of ranched reptiles has drastically increased, we need to work toward a better understanding of the impacts of ranching on wild populations and the future of commercially traded reptiles.

The Fat of the Matter: Regenerated Tails of Juvenile Leopard Geckos

Many lizard species store fat in their tails, and the loss of those fat stores after autotomy could be costly. Maximum caudal autotomy is frequently exhibited in juvenile lizards, with an accelerated rate of tail regrowth at the expense of normal body growth. After maximal autotomy, the regenerated tail lacks fracture planes and becomes a permanent structure, with possibly enhanced storage capacity. These authors test whether the regenerated tail of juvenile Leopard Geckos (*Eublepharis macularius*) is more effective at storing fat than the original tail. Juveniles were split into two groups: original tail and maximum caudal autotomy. Half of each group was then assigned to either a high or low diet regime. After 14 weeks, tail mass and volume, and cross-sectional areas of subcutaneous and inner fat, muscle, and skeletal (including cartilage) portions were calculated for 24 individuals. The authors predicted that, when accounting for body size, regenerated tails would be heavier (within a dietary regime) and contain more fat (regardless of dietary regime) than original tails. They also predicted that within a diet regime, regenerated tails would have a larger cumulative cross-sectional area relative to tail length than original tails. Lastly, they predicted that the skeletal and muscle components relative to body size of regenerated tails should not be different from original tails, regardless of dietary regime. Each of the first three predictions were supported, with regenerated tails being heavier, with greater cross-sectional area and more subcutaneous fat than original tails. In these analyses, there was no significant effect of dietary regime. Additionally, regenerated tails from individuals on a high dietary regime had more inner fat than all other groups. Regenerated tails had greater cross-sectional areas for all tissue types, not supporting the fourth prediction. Greater areas of muscle and skeletal tissue in regenerated tails may be an associated effect of the more massive, larger tails, or could be a secondary effect of the increased fat storage. The rapid tail regeneration in juvenile leopard geckos, preferentially allocating resources away from normal body growth and toward the tail, supports the occurrence of a trade-off. Juveniles deploy the whole tail, forsaking the ability for future autotomy for greater resource reserves. In contrast, adults autotomize a smaller portion of their tails, and the resultant regenerated tail is smaller in mass and volume than the original. The effects of the altered, regenerated tail form in juveniles on locomotion, reproductive success, and survival still require investigation.

Russell, A. P., S. E. Lynn, G. L. Powell, and A. Cottle. The regenerated tail of juvenile leopard geckos (Gekkota: Eublepharidae: *Eublepharis macularius*) preferentially stores more fat than the original. Zoology (*in press*) doi:10.1016/j.zool.2014.12.003

Testing the Bogert Effect in *Sceloporus*

Understanding how species adapt to climate change is critical for obvious reasons. Although behavioral thermoregulation might allow species to adapt to rising temperatures, it might also reduce genetic variation underlying physiological thermal tolerance. This hypothesis, dubbed the "Bogert effect" (for Charles Bogert), has been difficult to demonstrate in natural systems. The authors of this paper set out to assess thermal niche conservatism across the *Sceloporus undulatus* complex (Phrynosomatidae), a group of small lizard species distributed across much of the US. The authors first measured three metrics of thermal tolerance (thermal preference, critical minimum, and critical maximum) in the laboratory for eight populations, and gathered field-estimated thermal preference data from the literature. If these thermal tolerances are conserved despite considerable variation in local thermal environment, the authors contend this is evidence in support of the Bogert effect. The authors then generated four hypothetical strategies ranging from full thermoconformer to full thermoregulator, and using climate and thermal tolerance data, they estimated variation in mean thermal tolerances for the four strategies across the distribution of the complex. Finally, they evaluated how the lizards will fare in the face of predicted climate change, assuming their thermal physiology remains conserved. With one exception, the thermal tolerances estimated for these lizards were remarkably consistent, and observed variation was not consistent with climate variation. The one exception was a population from Texas, which had higher empirical thermal limits; this was also reflected in the authors' analyses, which determined that the region was too hot for populations to persist if the lizards were thermoregulators with strict thermal niche conservatism. Further, the extrapolation of expected thermal tolerance showed full thermoregulators could persist across the distribution of the complex with the same tolerances (allowing for conservation of tolerances) while scenarios with various degrees of thermoconformation could not. The predictions of how these populations will fare with projected climate change indicated populations exhibiting strict thermoregulation and conserved thermal tolerances will persist to a point, after which thermal tolerance evolution is necessary. This study shows that for these lizards, thermal niche evolution will be necessary to persist in the face of climate change; however, the buffering effect of thermoregulation may leave the populations with insufficient standing genetic variation for this to be possible.

Buckley, L. B., J. C. Ehrenberger, and M. J. Angilletta, Jr. 2015. Thermoregulatory behaviour limits local adaptation of thermal niches and confers sensitivity to climate change. Functional Ecology (*in press*) doi: 10.1111/1365-2435.12406

LETTERS TO THE EDITOR

WCH: Developing a Global Communication Network for Herpetologists

The World Congress of Herpetology (WCH) is an international organization whose primary goal is "**to promote international interest, collaboration and co-operation in herpetology.**" To date this has been achieved by successfully hosting seven world congresses in locations around the world (Fig. 1). The 8th WCH will be hosted in Hangzhou, China and will complete the location of these meetings in all zoogeographic regions of the world.

In addition to providing this important role, we are now inviting herpetologists around the world to join an exciting new WCH initiative to develop a global communication network for herpetologists. The objective is to provide a global framework linking individual herpetologists, with local, national, and regional herpetological societies around the world, using an integrated email, www sites, and social media networks.

The WCH Global Communication Network for Herpetologists has been initiated to provide a rapid form of communication among herpetologists around the world, linking students, professors, and professional herpetological organizations through the World Congress of Herpetology (Fig. 2).

Affiliated organizations form an important role within the WCH constitution (Fig. 3) and can facilitate opportunities to connect individual herpetologists around the globe. To promote regional participation in WCH activities, affiliated organizations are encouraged to nominate a member to represent their organization and region on the WCH International Herpetological Committee.

The global WCH communication network will disseminate information about:

- Local and national herpetology labs, and organizations, located within each region;
- Local, national, regional, and WCH conferences and workshops in herpetology;
- Studentships, scholarships, and volunteer opportunities for students in herpetology;
- Career opportunities such as postgraduate scholarships, postdoctoral positions, jobs for herpetologists;
- Research activities that have an international perspectives and global participation.

The WCH communication network will engage with affiliated individuals and organizations using all opportunities available.

JEAN-MARC HERO
Secretary General for the World Congress of Herpetology
Environmental Futures Research Institute, School of Environment, Griffith University, Australia; e-mail: m.hero@griffith.edu.au

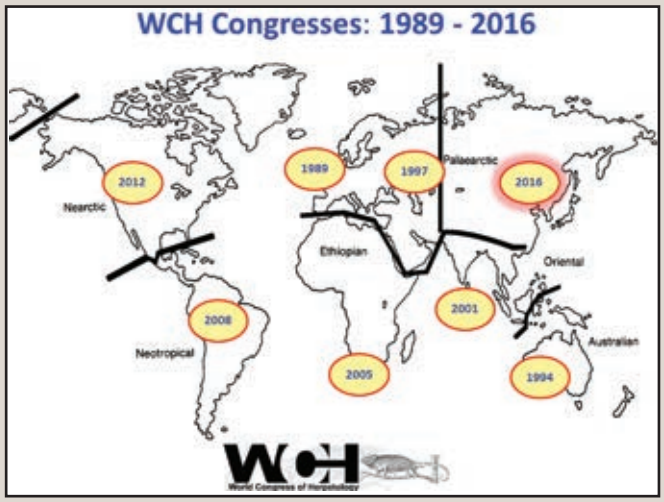

FIG. 1. Years and regional locations of the WCH congresses hosted between 1989 and 2012. The 8th WCH will be held in Hangzhou, China during 15–21 August in 2016.

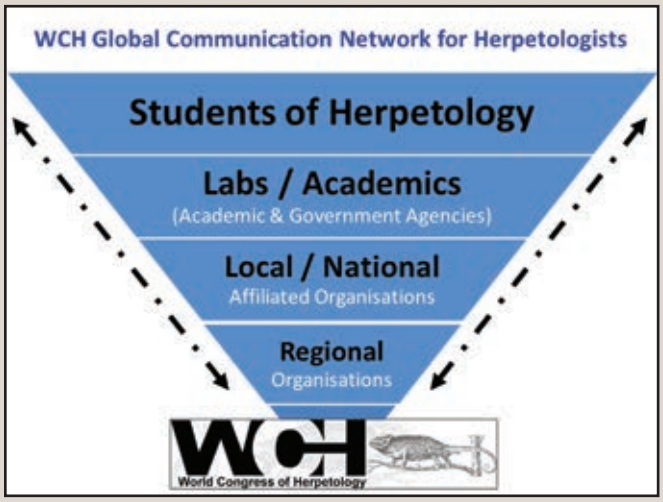

FIG. 2. A conceptual model for developing the WCH Global Communication Network for herpetologists. Individuals can link directly via Facebook and other social media, and organizations can share web pages and e-mail list servers.

Current media include:

1. Active links between websites, including both organizations and individual labs organized within regions, via an interactive global map on the WCH website (WCH URL: http://www.worldcongressofherpetology.org/);
2. Reciprocal sharing of logos on our respective websites;
3. Linking Facebook pages via the WCH Facebook page; (https://www.facebook.com/pages/World-Congress-of-Herpetology/141951465828807).
4. Actively disseminate information using social media networks (e.g., WCH Twitter hashtag: #WCHerpetol);
5. Provide email notifications to individual herpetologists around the world, distributing through individual, local, and regional email list-servers.

In my role as WCH Secretary General, I would like to personally invite individuals and organizations to join this network, and where possible, encourage your local organization to become "Affiliated" with the World Congress of Herpetology.

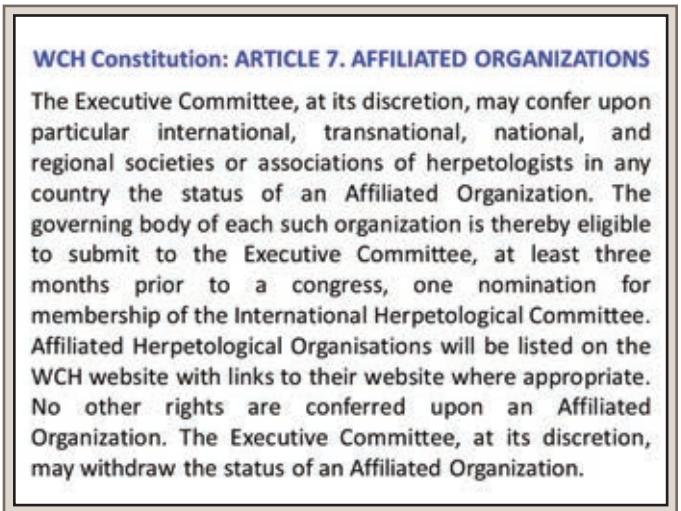

FIG. 3. An extract from the WCH constitution outlining the role of "Affiliated Organizations."

FIG. 4. First advertisement for the 8th World Congress of Herpetology to be held in Hangzhou, China during 15–21 August 2016.

If your organization joins this exciting new initiative, I would also invite your organization to appoint a "WCH Representative" to provide an active link between WCH and your organization. The primary role of the nominated WCH Representative would be to share and pass on information from your society membership to the WCH and vice-versa (through a regional hub). The WCH Representative will be a direct link for communication and will mediate the flow of information to the broader community, and ensure that only relevant professional information is transmitted in either direction. The WCH Representative would organise and nominate regional candidates for other WCH initiatives such as the "WCH awards in Herpetology," and the "WCH Hall of Fame." WCH Representatives are encouraged to nominate for positions on the WCH committees, and attend WCH meetings (Fig. 4).

Please consider this invitation as an inclusive opportunity to internationalize and strengthen herpetology. I look forward to engaging with individuals and organization representatives to develop a WCH communication network linking herpetologists around the world.

FINAL REMINDER !

UNIVERSITY OF KANSAS SSAR MEETING

DATES: THURSDAY, JULY 30 – MONDAY, AUGUST 3, 2015

co-sponsored by Partners in Amphibian and Reptile Conservation (PARC)

together with the herpetological societies of Kansas, Missouri, and Arkansas, the Center for North American Herpetology, *and the* International Society for the History and Bibliography of Herpetology

• For registration and full conference details, visit SSAR2015.ku.edu •

RECEPTION FOR DISTINGUISHED SENIOR HERPETOLOGISTS

At the 1996 SSAR meeting at KU, a special reception that honored Roger Conant, Henry S. Fitch, and Hobart M. Smith allowed students to meet and converse with these giants of our field. We are expanding this highly popular event for the 2015 meeting to enable all participants to meet and honor a distinguished group of today's seniors. The following have confirmed or indicated that they hope to attend:

Bayard Brattstrom
William Duellman
Harold Dundee
Richard Etheridge
Itzchak Gilboa
Harold Heatwole
Victor Hutchison
Alan Leviton
Janis Roze
Jay Savage
David Wake
Kenneth Williams
John Wright

SSAR SYMPOSIA

BONES, FROGS, AND EVOLUTION

Organized by David Blackburn, Anne Maglia, and David Cannatella

•

FRONTIERS IN INTEGRATIVE ORGANISMAL BIOLOGY: HERPETOLOGICAL HORIZONS

Organized by Rich Glor and Rafe Brown

SSAR WILL HOLD ITS 2015 MEETING ON the beautiful and centrally located campus of the University of Kansas in Lawrence. All scientific sessions will be held in the Kansas Union, which is adjacent to the KU Biodiversity Institute and Natural History Museum, the setting of more than a century of research and graduate education in herpetology. The intimate setting will facilitate friendly interactions while lowering fees for registration and lodging.

This unique campus-based meeting will include oral and poster presentations, silent and live auctions, vendor displays, student social, symposia (see left column), and special lectures (see right column).

Conference activity highlights include:

- Redesigned audiovisual shows arranged by David Dennis and Eric Juterbock.
- Reception honoring distinguished senior herpetologists, allowing students to interact personally with luminaries in our field. (see names at left)
- Herpetological Quiz, arranged by the graduate students at the University of Texas at Arlington and KU. Separate student and professional categories, with prizes to the winners.
- Guided tours of herpetological collections and newly renovated laboratories in the Biodiversity Institute.
- Tours of the Fitch Reservation at the KU Biological Fieldstation and Reserves, led by George Pisani.
- Special presentations for the International Society for the History and Bibliography of Herpetology, featuring author Sally Haines of the KU Spencer Research Library.
- Display of live Kansas herps with photographic set-ups.

NOTICE ABOUT PICNIC: Dinner on the final day of the meeting is an outdoor picnic. When registering, keep in mind that *picnic tickets must be purchased before arrival at KU* because final numbers have to be confirmed a week in advance of the event.

FEATURED SPEAKERS

KEYNOTE LECTURER

David Hillis

New Herpetological Circular from the Society for the Study of Amphibians and Reptiles
Herpetological Circular 42

HERPETOLOGICAL COLLECTING AND COLLECTIONS MANAGEMENT
THIRD EDITION
BY
JOHN E. SIMMONS

This is the 3rd edition of this popular herp circular. John Simmons has greatly expanded the information on the history of collections, laws and permits needed for collecting in the US and Internationally. The Collection Management section covers the most up to date techniques for preparing, curating, and storing specimens and associated data.

Appendices provide extensive checklists for herpetological collecting trips, equipment suppliers for specialty field and collection materials, and agency contact information.

June 2015 ISBN 978-0-916984-90-8 191 pp.

HC 42 Prepublication (SSAR members only)			
first copy -	US $14.00	USA Shipping : First copy	US $4.00
After Nov. 30, 2015	US $20.00	Additional copies	US $3.00

Send orders to: Breck Bartholomew, SSAR Publications Secretary, P.O. Box 58517, Salt Lake City, UT 84158-0517, USA. Telephone / fax 801-562-2660; email: ssar@herplit.com. Make checks payable to "SSAR." Overseas orders must be paid in USA funds using a draft drawn on American banks or by International Money Order. Orders may be charged to VISA or MasterCard (Account number and expiration date must be provided). SSAR membership details and a complete list of Society publications can be obtained on request from the Publications Secretary.

Cover Images for *Herpetological Review*

We are looking for photographic images to appear on future covers of *HR*. To be considered, preferred images should have the following qualities:

- Should be technically superior photographs (e.g., composition, lighting, etc., should be excellent; subject must be in focus).
- Should be taken in vertical format, or, if in landscape format, permit cropping to achieve a vertical orientation (2550 × 3300 ppi).
- Should be based on film or digital media; if the latter, the native resolution must be sufficiently high to permit cropping and/or enlargement to print publication quality.
- Preference will be given to images that depict poorly known species. These could include recently described taxa or species for which a color illustration has never been published.
- Preference will be given to images that communicate some aspect of the biology of the organism (e.g., predation, feeding, courtship, crypsis).
- Images should not have been published previously nor concurrently submitted for publication elsewhere (print or electronic media).

Images for consideration should be submitted as low-resolution jpg or pdf files. Do not send full resolution images unless requested to do so. All submissions or questions should be directed to the Editor (herpreview@gmail.com).

INFORMATION FOR CONTRIBUTORS

Herpetological Review is a peer-reviewed quarterly that publishes, in English, articles and notes concerning the study of amphibians and reptiles, as well as book reviews, commentaries, regional and international herpetological society news, and letters from readers directed to the field of herpetology. Articles reporting the results of experimental research, descriptions of new taxa, or taxonomic revisions are not published in ***HR***, but should be submitted to the ***Journal of Herpetology*** (for information, please refer to: http://www.ssarherps.org/pages/JHinstr.php). To submit a manuscript to ***HR***, please consult the SSAR webpage at:

http://ssarherps.org/publications/journals/herpetological-review/

REPRINTS AND PAGE PROOFS

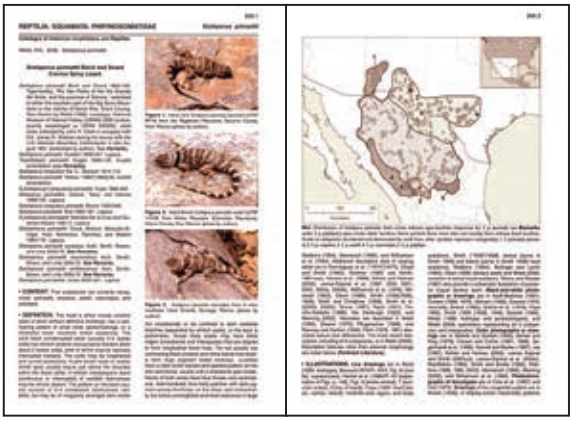
Page proofs are sent electronically to authors of all articles, book reviews, and obituaries, but are not prepared for natural history, geographic distribution, or herpetoculture notes. Proofs are sent as pdf files approximately 2–4 weeks prior to publication. High resolution electronic (pdf) reprints of notes, articles, book reviews, and obituaries are provided at no charge to the primary/corresponding author as a benefit of SSAR membership. Reprint files will normally be sent prior to the issue mailing date from the printer. Authors who are not current SSAR members may purchase pdf reprints from the SSAR Publications Office.

ADVERTISING

Herpetological Review accepts commercial advertising. Rates and copy information are available from the SSAR web page (http://www.ssarherps.org/pages/HRinfo.php).

Herpetological Review (ISSN: 0018-084X) is published quarterly (March, June, September, and December) by the Society for the Study of Amphibians and Reptiles at the Department of Natural Sciences, Williams Baptist College, P.O. Box 3692, Walnut Ridge, AR 72476, USA. Periodicals postage paid at Walnut Ridge, AR 72476 and at additional mailing offices.

All rights reserved. No part of this periodical may be reproduced without written permission of the Editor, except that authors and their agents are permitted to reproduce and distribute their own articles and notes.



POSTMASTER: Send address changes to Breck Bartholomew, SSAR Publications Secretary, P.O. Box 58517, Salt Lake City, UT 84158. **MISSING OR DAMAGED ISSUE?** Please notify Breck Bartholomew, SSAR Publications Secretary (e-mail: ssar@herplit.com) for a replacement.

SSAR PUBLICATIONS

SSAR publishes seven different series: *Journal of Herpetology, Herpetological Review, Facsimile Reprints in Herpetology, Contributions to Herpetology, Herpetological Circulars, Herpetological Conservation*, and the *Catalogue of American Amphibians and Reptiles* (see below for CAAR details). SSAR members receive pre-publication discounts on all *Facsimiles* and *Circulars* and on volumes in the *Contributions* and *Herpetological Conservation* series. A complete pricelist of Society publications is available at: http://www.ssarbooks.com/.

CATALOGUE OF AMERICAN AMPHIBIANS AND REPTILES

The *Catalogue* consists of individual accounts of species and genera prepared by specialists, including synonymy, definition, distribution map, and comprehensive list of literature for each taxon. The accounts cover amphibians and reptiles of the entire Western Hemisphere. As of 2014, SSAR is making all CAAR accounts OPEN ACCESS as a service to the herpetological community. To access individual accounts, visit http://www.ssarcaar.com.

SOCIETY FOR THE STUDY OF AMPHIBIANS AND REPTILES

www.ssarherps.org

The Society for the Study of Amphibians and Reptiles, the largest international herpetological society, is a not-for-profit organization established to advance research, conservation, and education concerning amphibians and reptiles. Founded in 1958, SSAR is widely recognized today as having the most diverse society-sponsored program of services and publications for herpetologists. Membership is open to anyone with an interest in herpetology—professionals and serious amateurs alike—who wish to join with us to advance the goals of the Society.

All members of the SSAR are entitled to vote by mail ballot for Society officers, which allows overseas members to participate in determining the Society's activities; also, many international members attend the annual meetings and serve on editorial boards and committees.

All members and institutions receive the Society's primary technical publication, the *Journal of Herpetology*, and its bulletin, *Herpetological Review*; both are published four times per year. Members also receive pre-publication discounts on other Society publications, which are advertised in *Herpetological Review*.

To join SSAR or to renew your membership, please visit the secure online ZenScientist website via this link:
http://www.ssarherps.org/pages/membership.php

Cryptic species are often difficult to study and recognize, especially when little morphological criteria are available to help distinguish between closely related species. Although congeners may be very similar in appearance, combining genetic analyses with differences in mating calls and breeding phenology may allow for new distinct species to be recognized and properly identified (Newman et al. 2012). Frogs within the genus *Pseudacris* are a good example of this. The Boreal Chorus Frog (*Pseudacris maculata*) and the Western Chorus Frog (*P. triseriata*) are two North American species that are extremely similar in size and coloration, which has created taxonomic confusion in the past (Platz 1989; Klaus and Lougheed 2013). To distinguish the two species, the ratio of the tibia length to the snout-to-vent length (SVL) has been used as a criterion of discrimination. *Pseudacris triseriata* has a slightly larger ratio of 42.6, whereas *P. maculata* has a ratio of roughly 39.3 (Smith 1956). With the two species so similar in size and shape however, tibia/SVL ratios could overlap and lead to species misidentification. An alternate identification criterion often used in the field is the playback of each species' display call during the breeding season. Although each species' song may initially sound very similar, *P. maculata* has been found to have a longer call with a lower pulse rate, whereas *P. triseriata*'s call is much shorter and has double the pulse rate (Platz 1989).

The first studies that delineated the range limits of *P. maculata* and *P. triseriata* were largely based on the morphometric measures of the tibia/SVL ratio, and did not include any song playback analyses (Smith and Smith 1952; Smith 1956). These studies determined *P. maculata*'s range to extend in latitude from the central US into Canada, and in longitude from the Rocky Mountains to northwestern Ontario. *Pseudacris triseriata*'s range included Ontario's extreme southern end, southwestern Québec, and several US states surrounding the Great Lakes (Smith and Smith 1952; Smith 1956) (Fig. 1A). However, recent studies based on species identification through breeding call and molecular-based analyses indicate that *P. maculata*'s range may extend further east than once believed, and raises some important questions about the true range of both species (Fortin et al. 2003; Lemmon et al. 2007a; Ouellet et al. 2009). Furthermore, although contact zones between the two species have not yet been identified, Lemmon et al. (2007b) determined that range overlap is highly likely to occur in southeastern Ontario, and stressed the importance of considering this geographic area when conducting *Pseudacris* biodiversity studies.

Initial range delineation studies did not extend *P. maculata*'s range into southern Ontario nor into Québec. The two species were believed to be allopatric until *P. maculata* populations were identified through song analysis along northern Québec's James Bay area (Fortin et al. 2003; Ouellet et al. 2009). Lemmon et al.'s (2007a) phylogenetic analysis of North American *Pseudacris* species using two mtDNA genes (12S and 16S), also proposed a new distribution of *Pseudacris* tree frogs in the United States and southern Ontario (Canada). According to this study, the distribution of *P. triseriata* would be limited to the United States and to Ontario's extreme southern end, but *P. maculata* would have a larger distribution in southeastern Canada (Fig. 1B). This recent molecular work raises questions as to whether previous range map studies using tibial bone measures may have misidentified *P. maculata* for *P. triseriata* in eastern Canada.

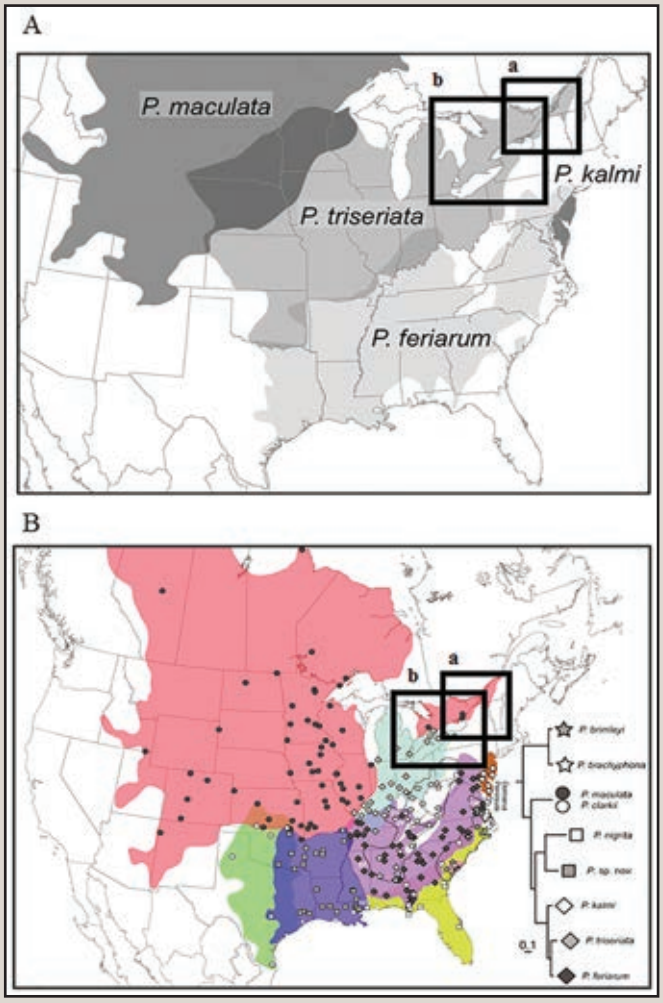

FIG. 1. A) Original *Pseudacris* range maps delineated by Smith and Smith (1952) and Smith (1956) predominantly using tibia/snout-to-vent length ratios. B) New phylogeny-based range delineation suggested by Lemmon et al. (2007a) using mitochondrial DNA. Source of maps: Lemmon et al. (2007a). Reproduced with permission by the copyright owner. Areas labeled as "a" and "b" delineate the location of our study sites within Québec and Ontario, respectively.

In light of Lemmon et al.'s (2007a) work, NatureServe (2014) now identifies chorus frog populations in eastern Canada to be composed of *P. maculata* instead of *P. triseriata*, but thorough revisions of the two species' range boundaries are necessary, especially considering the rapid decline of chorus frogs in Québec and Ontario (Seburn et al. 2008).

As of March 2000, the Québec government classified what was always believed to be *P. triseriata* frog populations as Vulnerable. A recovery plan and several habitat conservation plans have since been created and partially implemented to help conserve remnant populations (Équipe de rétablissement de la rainette faux-grillon de l'ouest 2000; Angers et al. 2007, 2008a, 2008b). Due to the major population declines that have been documented in Québec and Ontario since 2002, the Great Lakes-St. Lawrence-Canadian Shield chorus frog population has been classified as Threatened by the Committee on the Status of Endangered Wildlife in Canada (COSEWIC), and is listed in Schedule 1 of the Species at Risk Act (SARA) (COSEWIC 2008). The status of *P. maculata* populations has not yet been evaluated by COSEWIC. They are however, listed as endangered in Vermont (USA) (Ferguson 2013) and critically imperiled in Michigan (NatureServe 2014). Populations have also been found to be declining in New York (USA) (Corser et al. 2012), in Ontario and along James Bay in northern Québec (Desroches et al. 2010).

The objective of this study was to help establish the true eastern distribution of *Pseudacris* chorus frogs by conducting a distance-based clustering analysis of individuals from southeastern Ontario, from along the Québec/Ontario border, and from several sites located in southwestern Québec. Individuals from various parts of the USA were also included in the analysis for comparison purposes. Species identification was further confirmed at each site using a non-genetic method of anuran identification of breeding call playback analysis. Shedding light on the true range of *Pseudacris* in southeastern Canada will help federal and provincial management practices protect the remaining fragile chorus frog populations found at the limit of their distribution, and will help determine the true identity of chorus frogs in southeastern Canada.

METHODS

Sites and sampling.—We sampled various localities within several major regions of Québec and Ontario (Canada). In southern Québec, four sites were sampled in the Outaouais region: two in 2006 near the municipality of Chelsey (U12) and in eastern Gatineau (U3), and two in 2009 in LuskVille (A11) and near Chatham (A12). In southern Québec's Montérégie region, frogs from five sites were collected in the spring of 2007: Boucherville (BOU), Brossard (BRO), Boisé du Tremblay (BT), La Prairie (LP), and Île Perrot (IP). Individuals from four sites in Ontario were also collected in 2009: Almonte (DW), Arnprior (ARN), Lake Opinicon (OP), and Cataraqui Park near Kingston (CA) (Fig. 2). An additional eight sequences of both *P. triseriata* and *P. maculata* individuals were retrieved from GenBank and were included in the dataset for comparison purposes (Table 1).

We played breeding call recordings of both *P. maculata* and *P. triseriata* at each site and noted which species responded. Sites were originally selected by listening to breeding calls from a distance, yet upon arrival at each site, the frogs were disturbed and their calls were silenced. Sitting silently for approximately thirty minutes allowed the frogs to resume their normal activities. We had two different breeding call recordings for each species, stored and played from an Apple iPod touch (©2007 Apple Inc.). The recordings were obtained from the Canadian Amphibian and Reptile Conservation Network, both online (FrogWatch) and on CD (EMAN/RESE). We proceeded to play one *P. triseriata* breeding call recording for three minutes, followed by an additional three minutes of silence used to note whether a response occurred. This was then repeated using the breeding call of *P. maculata*. The entire procedure was subsequently carried out again using the second breeding call recording we had available. To avoid introducing bias, the procedure was immediately repeated playing *P. maculata* recordings first, followed by *P. triseriata* recordings. Additionally, we alternated the order of which species' playback recordings were first played in successive sites. Recordings were played at each site in 2007 and 2009, and were carried out at approximately 1500 h.

A varying number of individuals were caught by hand from each site (N = 19–25); those samples are currently undergoing a population genetics analysis as well (N. Tessier, pers. obs.). For each individual captured, a toe clip was removed with disinfected scissors and stored in 95% ethanol at room temperature. The

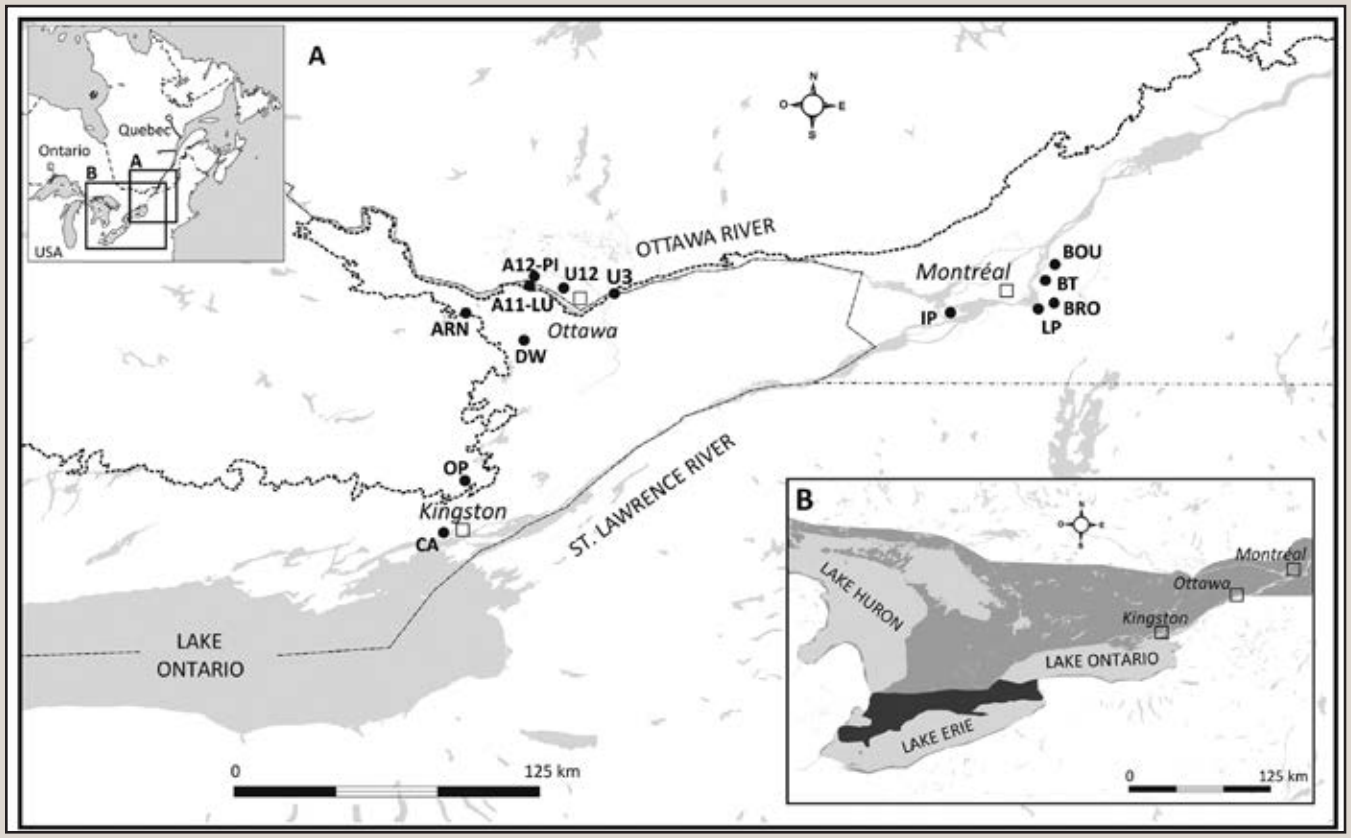

FIG. 2. Geographic location of all chorus frog sampling sites included in this study. In Québec's Outaouais region: Chelsey (U12), Gatineau (U3), LucksVille (A11), and Chawtham (A12). In Québec's Montérégie region: Boucherville (BOU), Brossard (BRO), Boisé du Tremblay (BT), La Prairie (LP), and Île Perrot (IP). Individuals from Ontario: Almonte (DW), Arnprior (ARN), Lake Opinicon (OP), and Cataraqui Park near Kingston (CA). The Carolinian and Great Lakes - St. Lawrence - Canadian Shield faunal provinces are depicted in dark and medium gray, respectively.

TABLE 1. Location and GenBank accession numbers for the 16 reference *Pseudacris* individuals included in this study.

Species	Accession Number	Location	State/Province & Country
Pseudacris maculata	AY291089	McKinley	New Mexico, USA
Pseudacris maculata	AY291090	Douglas	Kansas, USA
Pseudacris maculata	AY291083	Archuleta	Colorado, USA
Pseudacris maculata	AY291082	Lac Seul	Ontario, Canada
Pseudacris maculata	AY291080	Gunnison	Colorado, USA
Pseudacris maculata	EF472135	Christian	Missouri, USA
Pseudacris maculata	EF472122	Jersey	Illinois, USA
Pseudacris maculata	EF472100	Bayfield	Wisconsin, USA
Pseudacris triseriata	AY291091	Berrien	Michigan, USA
Pseudacris triseriata	EF472157	Breckinridge	Kentucky, USA
Pseudacris triseriata	EF472156	Niagara	New York, USA
Pseudacris triseriata	EF472151	Logan	Ohio, USA
Pseudacris triseriata	EF472145	Niagara R.M.	Ontario, Canada
Pseudacris triseriata	EF472139	Daviess	Kentucky, USA
Pseudacris triseriata	EF472138	Perry	Illinois, USA
Pseudacris triseriata	EF472137	Montgomery	Tennessee, USA

scissors were disinfected with ethanol between each individual clipping. All frogs were then immediately released at the exact site of capture and were temporarily monitored to ensure that normal behavior ensued. Subsets of three to four individuals per site were then selected at random and used for further molecular identification.

Molecular analysis.—DNA was extracted using the Invitrogen™ PureLink™ Genomic DNA kit (Version A, February 2007) (Invitrogen™ Inc., Burlington, Canada). To verify the maternal lineage of the chorus frogs in our dataset, a 335-base pair (bp) portion of the 16S mitochondrial gene was sequenced for each individual using the 16S-1F and 16S-4R primers (Johnson et al. 1998). The 16S region is less conserved than the 12S region, thus has greater variability and is usually used for phylogenetic studies at the genus level (Hwang and Kim 1999). PCR amplifications were carried out in 50-mL volumes and included 100–200 ng of genomic template DNA per sample, 1.4X reaction buffer, 2.5 mM of $MgCl_2$, 0.35 mM of each dNTP, 0.22 µM of each primer, 0.5 units of *Taq* DNA polymerase (1 U ≈ 16.67 nkat), and 35.7 µL of sterile H_2O. Thermal cycling was carried out on a GeneAmp® PCR System 9700 (Applied Biosystems) under the following

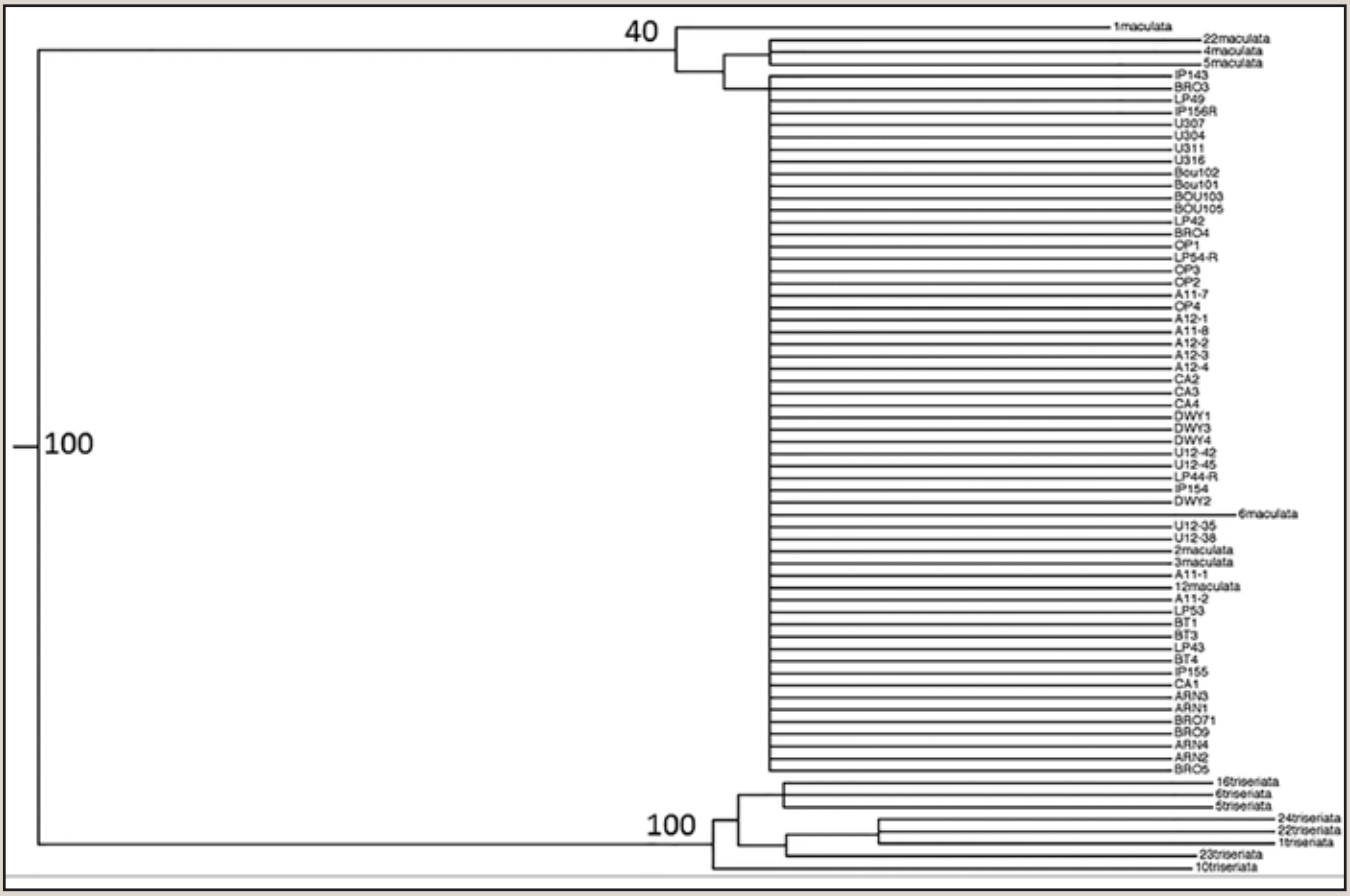

FIG. 3. Neighbor-joining tree constructed from the 335 bp 16S mtDNA gene sequence (strict consensus supported by 1000 bootstrap replicates and distances corrected with a Jukes-Cantor model). All 54 individuals found in Québec and Ontario are grouped with the eight *P. maculata* reference sequences, whereas the eight reference sequences for *P. triseriata* define a distinct group with 100% bootstrap support.

conditions: an initial denaturation of 94°C for 1 minute; 31–38 cycles of 94°C for 45 seconds, 50°C for 1 minute and 45 seconds, and 72°C for 1 minute and 30 seconds; and a final extension step of 72°C for 10 minutes. Amplification success was determined by staining the PCR products with SYBR® Green I nucleic acid gel stain (Invitrogen™ Inc., Burlington, Canada), running them on a 2% agarose gel, and revealing the bands under UV light. All PCR products were sent to the McGill University Génome Québec Innovation Centre for purification and sequencing using an ABI-3730XL DNA Analyzer (Applied Biosystems). Sequences were then visualized with 4PEAKS 1.7.2 (Mekentosj B.V., Aalsmeer, The Netherlands) and aligned with ClustalX (Thompson et al. 1997). All sequences were deposited in the GenBank public repository (accession numbers KM669659-KM669712).

Distance-based clustering analysis and species identification.—Aligned sequences were evaluated with jModel Test 2 v 2.1.5 (Darriba et al. 2012) to compare different DNA substitution models, and the Jukes-Cantor (JC) model (Jukes and Cantor 1969) was determined to be the best fit for our data. Accordingly, a neighbour-joining tree was then estimated from JC-corrected distances with 1000 bootstrap replicates to determine branch support. This tree was then used to determine the identification of the Québec samples with respect to the reference sequences of known identity. All clustering analyses were performed in R (R Development Core Team 2013) using the "ape" package (Paradis et al. 2004).

RESULTS

At every sampled site, chorus frogs responded to the playback recordings of *P. maculata* rather than those of *P. triseriata*. Frogs remained silent after *P. triseriata* recordings were played.

Mitochondrial gene.—The 16 reference sequences (8 *P. maculata* and 8 *P. triseriata* individuals) produced four haplotypes per species, and all Québec (N = 39) and Ontario (N = 15) individuals matched the *P. maculata* 1 haplotype (Table 2). A total of 14 variable sites were used to discriminate the two *Pseudacris* species, and the corresponding neighbor-joining tree is presented in Fig. 3. In this tree, all 54 individuals found in Québec and Ontario were grouped with the eight known *P. maculata* sequences. The eight *P. triseriata* reference sequences produced their own distinct group with 100% bootstrap support, therefore separation between the two species was highly supported.

DISCUSSION

Although the identification of *P. maculata* in Québec has only been observed in recent history, their populations were already established within the province, yet misidentified as *P. triseriata*. A number of studies based on breeding calls have found *P. maculata*'s northeastern range limit to extend 100 km eastward into northwestern Québec (Fortin et al. 2003; Ouellet et al. 2009), and genetic analyses have also confirmed its presence

in southeastern Ontario (Lemmon et al. 2007a). In our present study, 16S mtDNA sequence analysis, as well as chorus frog breeding call inventories in the peri-urban areas of the Greater Montréal and Outaouais regions of Québec, established for the first time that remnant chorus frog populations in southern Québec are actually comprised of *P. maculata* individuals rather than *P. triseriata*.

The aforementioned studies (along with the present one) strongly suggest that tibia/SVL ratios, on which the identification of *P. triseriata* and *P. maculata* individuals were based during the original delineation of their respective ranges, should be reconsidered as a reliable diagnostic criterion for species identification. Tibia/SVL ratios have long been used in taxonomy and systematics, yet little is known in terms of this measure's precision and accuracy. Rogers (2009) found that Boreal Toads required aggressive and awkward handling to take proper tibial and SVL length measurements, but errors in measurement still varied up to 30% within the same individual. He suggested that tibial and SVL measurements should be used to construct rough size indices rather than for precision, and that the gape width measurement method yielded better results. Hayek et al. (2001) also recommend employing anuran morphometrics for rough rather than precise measurements, and to use caution when drawing biological inferences from these data. Climatic conditions may also play a role in intraspecific SVL measurements. *Pseudacris regilla* was found to significantly fluctuate in SVL measurements when exposed to differing weather conditions (e.g., temperature, altitude, and rainfall) (Calhoon and Jameson 1970). With climate change becoming increasingly important to consider in amphibian genotypic/phenotypic studies (Spear et al. 2012), it is a variable that must be taken into account when employing tibia/SVL ratios for species identification purposes.

In the very first studies to delineate *Pseudacris* range limits (Smith and Smith 1952; Smith 1956), all measurements were taken on preserved specimens. However, Bleakney (1959) found that even the most carefully preserved chorus frog specimens will exhibit a body length decrease of 1–3 mm, but whose tibia length will only decrease between 0–1 mm. Furthermore, the initial delineation studies did not incorporate song playback recordings when identifying chorus frogs. Playback methods were first pioneered in the mid-1960s by Capranica (1965; 1966). Breeding call playbacks have shown to successfully identify several different anuran species within the same habitat (Sung et al. 2005; Acevedo and Villanueva-Rivera 2006), however these methods were not as robust for population size and abundance estimates (Corn et al. 2000), even for *P. maculata* (Corn et al. 2011). Call playbacks of a single mating call (rather than a chorus of breeding calls) have proven most efficient in obtaining responses from resident frogs, and allow researchers to easily access a wide range of habitats that otherwise might be physically difficult to work in when using capture methods of identification (Sung et al. 2005). On the other hand, the use of recording devices and speakers may be costly; however, the methods and devices employed in this study proved to be cost-efficient without undermining the effectiveness of the breeding call recordings and responses.

Our findings have several implications for the conservation and research of Canadian *P. maculata* and *P. triseriata* populations. First, they suggest that the Great Lakes-St. Lawrence-Canadian Shield chorus frog population should be renamed a *P. maculata* population. This population was originally named as a *P. triseriata* frog population by the COSEWIC, listed under

TABLE 2. Polymorphic nucleotide positions for the Western Chorus Frog (*Pseudacris triseriata*) compared to its congener species, the Boreal Chorus Frog (*P. maculata*) using the Genbank 16S mtDNA sequences (8 *P. maculata* and 8 *P. triseriata* individuals). The sequences produced four haplotypes per species, but 14 variable sites helped distinguish *P. maculata* from *P. triseriata*. All Québec and Ontario specimens (N = 54) matched the *P. maculata*1 haplotype. Nucleotides identical to the *P. maculata*1 haplotype are indicated with a period (.).

SARA, and represents an Evolutionary Significant Unit (ESU) for conservation. Considering the scenarios of dispersal routes for *P. maculata* (Lemmon et al. 2007b) and their disjunct population distribution in Canada, the Great Lakes-St. Lawrence-Canadian Shield population may have evolved in isolation, but this assertion requires further investigation. Consequently, this population's status should be re-evaluated separately from that of *P. maculata* populations further west into Canada. Moreover, comparative studies between chorus frogs from Québec and Ontario are needed to determine if locally adapted phenotypic traits (e.g., difference in advertisement call structure), or if differences on a finer genetic scale (e.g., population genetic analyses) have evolved. In their phylogenetic study of the trilling chorus frogs, Lemmon et al. (2007a) found *P. maculata* and *P. clarkii* to show significant differences in morphology and behavior, but were undifferentiated with respect to their mitochondrial DNA. In terms of a fine scale genetic analysis, we are currently employing a population genetics analysis to help determine the level of genetic differentiation and isolation of this important ESU (N. Tessier, pers. obs.).

Although not much is known about *P. maculata*'s overall population stability, individuals located at the edge of their range limits are often found in sub-optimal habitats and experience greater environmental fluctuations, which increases their vulnerability (Gaston 1990; Mott 2010). Therefore, Québec chorus frogs in particular, whose populations have been disappearing and whose situation has become precarious, should be monitored closely. Multiple studies have tracked the rigorous population decline of chorus frogs in the Montérégie and Outaouais regions of Québec, and argued that urgent conservation actions need to be taken to save them from extinction (Bonin and Galois 1996; Picard and Desroches 2004; Angers et al. 2008a, b; COSEWIC 2008; Seburn et al. 2008; Équipe de rétablissement de la rainette faux-grillon de l'ouest 2010). Since the 1950s, Québec has seen a 37% decrease in chorus frog population size every ten years, and the decline is expected to continue (COSEWIC 2008; Équipe de rétablissement de la rainette faux-grillon de l'ouest 2010). Chorus frog population surveys in Ontario indicate a 42.6% decline in abundance over the last decade despite hosting areas where chorus frogs seem relatively abundant (COSEWIC 2008).

The greatest threat to these chorus frog populations is the progressive destruction and modification of their habitat for land use, development, and urbanization—an endless process primarily driven by economic and population growth (Trauger et al. 2003). Currently, less than 10% of viable chorus frog habitats are located in federally or provincially protected parks and refuges, leaving most populations vulnerable to the increased anthropogenic pressures (Environment Canada 2010). The long-term protection of remnant habitats is key for ensuring their continued survival.

Acknowledgments.—A special thank you goes to Pierre Bilodeau, Lyne Bouthillier, Jocelyn Carron, Caroline Gagné, Sylvain Giguère, Patrick Labonté, Yong Lang, Isabelle Lefebvre, Martin Léveillé, Tommy Montpetit, Roxane Pétel, Daniel St-Hilaire, and Tommy St-Onge. We would like to thank the McGill University Génome Québec Innovation Center for technical assistance, and the staff at the Ministère des Ressources naturelles (MRN), Ministère de Développement durable, Environnement, Faune et Parcs (MDDEFP) and Environment Canada for fieldwork help. This study was supported by funding from Environment Canada and from the Strategic Technology Applications of Genomics in the Environment (STAGE) program. All procedures were approved by the Québec and Ontario government (Québec, Montérégie #2006-05-195-122-16-SF & #2007-11-25-750-16-SF; Québec, Outaouais #2006-04-18-003-07-SF & #2009-04-20-006-07-SF; Ontario WSCA #1051126 April 2009), and all proper animal care permits were acquired (Université de Montréal, Permis de bons soins #05-069 & #09-039).

Natural Hybridization of Triploid Normally Parthenogenetic *Aspidoscelis exsanguis* with Gonochoristic *A. inornata* (Squamata: Teiidae) and Identity of an Associated Specimen

Triploid parthenogenetic *Aspidoscelis exsanguis* (Chihuahuan Spotted Whiptail) is an abundant and widely distributed lizard in parts of Arizona, New Mexico, and Texas in the southwestern United States, and Sonora and Chihuahua in northern Mexico (Degenhardt et al. 2005; Dessauer and Cole 1989). It was derived in a two-step hybridization sequence (Table 1) which could have involved either *A. costata* x *A. inornata* → unknown diploid parthenogenetic species then many generations later before extinction x *A. septemvittata* → *A. exsanguis* (see Good and Wright 1984; Moritz et al. 1989) or *A. burti* x *A. inornata* → unknown diploid parthenogenetic species then many generations later before extinction x *A. scalaris* → *A. exsanguis* (see Dessauer and Cole 1989; Moritz et al. 1989).

Only two of the several gonochoristic species with which *A. exsanguis* is syntopic, namely *A. inornata* (Little Striped Whiptail) and *A. sexlineata viridis* (Prairie Racerunner), have been reported to hybridize with this triploid normally parthenogenetic species (Table 1). Walker et al. (2006) reported a tetraploid male of *A. exsanguis* x *A. sexlineata viridis*, based on well-developed reproductive structures, external morphology, and color pattern, from De Baca County, New Mexico, deposited in the University of Arkansas Department of Zoology Collection (UADZ 6241). This report pertains to our study of the only known tetraploid lizard directly verified by a karyotype to have originated as a naturally occurring hybrid of *A. exsanguis* x *A. inornata*, a female deposited in the Harvard Museum of Comparative Zoology (Neaves 1971). It is one of only four genetically confirmed tetraploid hybrids of *Aspidoscelis* reported to date (see Hardy and Cole 1998). In addition to describing the morphology and color pattern of this unique biological novelty (Figs. 1R, 2M) using characters and terminology not considered by Neaves (1971), we compare it with samples of its parental species. We also provide a hypothesis to account for the aberrant dorsal color pattern of the tetraploid hybrid, resulting from identification of another key specimen (Fig. 1L) deemed problematic by Neaves (1971). Finally, the results of this study could also help detect possible natural independently reproducing tetraploid parthenogenetic lineages (= IRTPL) derived from hybridization between these species as have been generated in the laboratory by Lutes et al. (2011).

Materials and methods.—We examined 19 specimens of *Aspidoscelis* loaned by the Harvard Museum of Comparative Zoology (MCZ) collected from Otero County, western New Mexico, in late August 1967 by W. B. Neaves. We measured the snout vent length (SVL) of each specimen to the nearest mm. For assessment of dorsal color patterns in *A. exsanguis*, *A. inornata*, and the hybrid between the two species (Figs. 1R, 2M), we employed terminology for pale stripes, intervening dark-hued fields, and small light-hued markings recommended by Burt (1931), Duellman and Zweifel (1962), and Walker et al. (2009). On each side of the body of a lizard (ventrolateral to dorsal) were lateral, dorsolateral, and paravertebral stripes with the latter exhibiting uneven margins in most specimens of *A. exsanguis* and being straight-edged in most *A. inornata*. With the exception of two six-striped lizards (i.e., each one lacking a vertebral stripe), specimens of *A. inornata* examined from Alamogordo in the MCZ collection either had a partial or a complete seventh stripe, the vertebral, between the paravertebrals (Fig. 2L). A vertebral stripe was not present in any of the *A. exsanguis*, which is typically six-striped (Fig. 2R). The fields on each side of the body in both species were identified as lower lateral (ventral to the lateral stripe), upper lateral (dorsal to the lateral stripe), dorsolateral (dorsal to the dorsolateral stripe) and vertebral (dorsal to the paravertebral stripe). The paravertebral stripes separately extended onto the base of the tail in *A. exsanguis*, but merged into a single stripe on the base of the tail in *A. inornata*

FIG. 1. An aberrantly patterned preserved male of *Aspidoscelis inornata* (MCZ R-100080; 53 mm SVL) is shown on the left; a tetraploid hybrid female of *A. exsanguis* x *A. inornata* (MCZ R-101991; SVL 68 mm) is shown on the right. Both specimens were collected from Alamogordo, Otero County, New Mexico, by W. B. Neaves, and recently photographed in the MCZ by Jon Woodward.

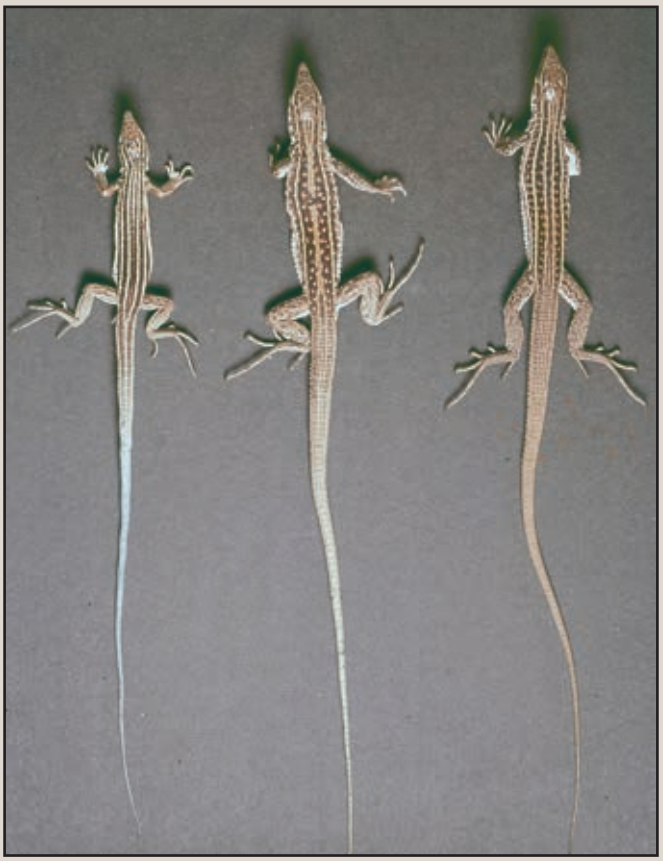

FIG. 2. A karyotyped tetraploid hybrid *Aspidoscelis exsanguis* x *A. inornata* (MCZ R-101991) is shown between its parental species, *A. inornata* (L) and *A. exsanguis* (R). Unlike *A. exsanguis*, the hybrid has larger and more distinct spots, evidence of separate paravertebral stripes only near the head and near the tail and joined in between, and had an intense blue coloration on the tail and ventral surfaces. Males of *A. inornata* typically also have vivid blue on these surfaces, no spots, joined paravertebral stripes only on the base of the tail, and typically a complete or partial vertebral stripe as shown. Females of *A. exsanguis* typically have six-stripes, unevenly margined paravertebral stripes, no vertebral stripe, and smaller spots than the hybrid. A version of this photograph and a description appeared in Neaves (1971).

(Figs. 1L, 2L). Whereas all *A. exsanguis* had a spotted dorsum, all *A. inornata* were unspotted (Figs. 1L, 2L).

Terminology and data for meristic characters examined, based on Duellman and Zweifel (1962), Manning et al. (2005), and Walker et al. (2009), in the hybrid, newly identified problematic specimen, and comparative material of *A. exsanguis* and *A. inornata* from Otero County are included in Table 2. The different numbers of observations for some characters resulted from previous damage to certain MCZ specimens. The qualitative scutellation characters examined in all specimens included size of the postantebrachial scales on the posterior aspect of each forearm, size of the mesoptychial scales along the edge of the gular fold (i.e., abruptly enlarged or not), and anterior extent of the circumorbital scale series on both sides of the head (see Duellman and Zweifel 1962). Statistical analyses of meristic variables (Table 2) in *A. exsanguis* and *A. inornata* were performed using JMP software (Version 11; SAS Institute, Inc., Cary, North Carolina, 2012) to generate a mean ± 1 SE, range of variation for each character, and determine statistical significance starting at $P = 0.05$

Results.—Walker and Lemos-Espinal (2015, *in press*) described four stages in the complex ontogenetic development of the dorsal color pattern in triploid *A. exsanguis*, with stage four in adults consisting of low contrast between either stripes or their fragments and fields, a profusion of spots on the stripes and in the fields, and spotted hind limbs. In the only known genetically confirmed, naturally occurring, tetraploid hybrid (4n = 92) of *A. exsanguis* x *A. inornata* (MCZ R-101991), the striped and spotted dorsal pattern resembled stage four of *A. exsanguis*, but it had been attained at a much smaller than usual body size (68 mm SVL) than described in that species. Moreover, it stood apart from the typical stage four dorsal patterns of *A. exsanguis* in that the elements of the pattern were not low contrast and the paravertebral stripes were consistently separated by a narrow dark-hued vertebral field only at each end of the body (Figs. 1R, 2M). This phenotypic trait of the hybrid, which was one of the characters that provided the basis for Neaves (1971) inferring its hybrid origin even before karyotypic analysis, bears a strong resemblance to the specimen of *A. inornata* (MCZ R-100080) with reference to the pattern of dorsal stripes in Fig. 1L. Another feature of the hybrid noted by Neaves (1971) was the intense blue coloration on the tail and ventral surfaces, which occurs in adult males of *A. inornata*, but not in adult females of either it or *A. exsanguis*.

The hybrid had enlarged and plate-like postantebrachial scales on the forearms, abruptly enlarged mesoptychial scales along the edge of the gular fold, and circumorbital scale series on each side of the head that extended anteriorly to the midpoints of the third supraocular scales. These characters unambiguously aligned MCZ R-101991with maternal parent *A. exsanguis*, albeit with an unusual color pattern. Use of a standard suite of meristic variables in MCZ R-101991 (see Manning et al. 2005; Walker et al. 2009) for comparisons with the samples of *A. exsanguis* and *A. inornata* revealed that data could not be obtained for the PV and PV/GAB because of a lack of separation of the paravertebral stripes at midbody (Figs. 1R, 2M; Table 2). The analyses also revealed that the GAB and COS counts for the hybrid were within the overlap in ranges of variation in these characters in both parental species. The OR count was positioned between the ranges of variation in the parental forms (Table 2). The SDL count for the hybrid exceeded the ranges of variation for both parental forms, and the FP and LSG counts for the hybrid was within the range of variation of only *A. exsanguis* (Table 2). Finally, the ILS count was below the ranges of variation in both parental species.

Neaves (1971) could not resolve the identity of specimen MCZ R-100080, collected from a syntopic association of *A. inornata* and *A. exsanguis* in Alamagordo, because of its unusual dorsal color pattern (Fig. 1L) and rudimentary reproductive organs. In actuality, it is a male of 53 mm SVL with very small testes. The postantebrachial scales on the forearms were granular in size, the mesoptychial scales along the edge of the gular fold were not uniformly abruptly enlarged, and the circumorbital scale series on each side of the head extended anteriorly only to the midpoints of the third supraocular scales. These characters identified MCZ R-100080 as a male of *A. inornata*, albeit with an unusual color pattern. With reference to striping pattern in *A. inornata*, the MCZ sample of eight specimens examined from Alamogordo (including the unusual male) comprised six specimens with seven stripes (i.e., six primary stripes plus either a complete vertebral or nearly so), one with six stripes (i.e., lacking a vertebral), and MCZ R-100080 with aberrantly joined paravertebrals except where separated intermittently and at each end of the body (Fig. 1L).

TABLE 1. Possible modes of origin proposed for the triploid parthenogenetic species *Aspidoscelis exsanguis*, and its hybrids with gonochoristic species.

Authors	Progenitors of Parthenospecies and Parents of Hybrid Combinations
Good and Wright (1984)	*A. costata* x *A. inornata* → 2n parthenospecies (then generations later) x *A. septemvittata* → *A. exsanguis*
Dessauer and Cole (1989)	*A. burti* x *A. inornata* → 2n parthenospecies (then generations later) x *A. scalaris* → *A. exsanguis*
Neaves (1971)	*A. exsanguis* x *A. inornata* → natural 4n ♀ hybrid (N = 1)
Lutes et al. (2011)	*A. exsanguis* x *A. inornata* → laboratory self-sustaining 4n parthenospecies
Walker et al. (2006)	*A. exsanguis* x *A. sexlineata* → natural 4n ♂ hybrid (N = 1)

TABLE 2. Summary of data for meristic characters and SVL for a sample of *Aspidoscelis inornata*, unusually patterned *A. inornata* (MCZ R-100080), tetraploid hybrid *A. exsanguis* x *A. inornata* (MCZ R-101991), and sample of *A. exsanguis* from Alamogordo, Otero County, New Mexico, collected by W. B. Neaves. Data for the two species are mean ± SE (first row) and range of variation and (N) (second row); included for each individual specimen is either a single datum for analyzable characters or ND for no data possible. Means ± SE followed by the same superscripted letters are not significantly different at $P = 0.05$.

Meristic Character	*A. inornata*	100080	101991	*A. exsanguis*
GAB: scales around midbody from one lateral row of ventral scales to opposite row of laterals	63.1 ± 0.67^{B} 61–66 (8)	64	66	69.0 ± 1.02^{A} 65–74 (10)
OR: dorsal granules from the occipital scales to the first row of caudal scales	159.3 ± 2.17^{B} 153–163 (4)	153	170	182.0 ± 1.76^{A} 178–187 (5)
PV: dorsal granules between the paravertebral stripes at midbody	7.8 ± 0.92^{A} 2–10 (8)	2	ND	4.7 ± 0.21^{B} 4–6 (10)
FP: femoral pores summed from both sides of body	31.2 ± 0.79^{B} 28–34 (6)	31	38	35.3 ± 0.24^{A} 33–38 (10)
SDL: subdigital lamellae of the fourth toe of the left pes	29.4 ± 0.92^{B} 28–32 (8)	29	34	30.9 ± 0.23^{A} 30–32 (10)
COS: circumorbital scales, summed from both sides of body	9.5 ± 0.67^{A} 8–12 (6)	12	10	8.9 ± 0.39^{A} 7–11 (9)
LSG: lateral supraocular granules, summed from both sides of body	27.0 ± 1.52^{B} 16–27 (8)	27	30	29.1 ± 0.84^{A} 25–32 (9)
ILS: interlabial scales, summed from both sides of body	26.4 ± 0.70^{A} 21–34 (7)	24	13	17.7 ± 0.60^{B} 15–21 (9)
SVL: snout to vent length	53.5 ± 1.89 45–61 (8)	53	68	67.6 ± 1.20 62–76 (10)

None of these specimens had spots in the dark-hued fields, lack of which is a consistent distinguishing character in *A. inornata* throughout its geographic range (Walker et al. 2009). Data for all meristic characters in the specimen, except the OR (Table 2), either were within the ranges of variation of both species (LSG) or were in the range for *A. inornata*, but within one to three scales of the lower or upper range limits of variation in *A. exsanguis* (i.e., GAB, PV, FP, SDL, COS, ILS). Nevertheless, the meristic alignment of MCZ R-100080 with *A. inornata* was indicated, and would not be unusual for range-wide samples of that species (Walker et al. 2012). In the case of the OR, this datum for the specimen marks the lower range limits for the sample of *A. inornata*, and was 25 scales below the lower range limit for *A. exsanguis* (Table 2); however, we have obvserved much lower OR counts in range-wide samples of *A. inornata*.

Discussion.—Arguably, the tetraploid karyotype confirming the hybrid origin of MCZ R-101991 via *A. exsanguis* x *A. inornata* in Alamogordo, Otero County, western New Mexico (Neaves 1971) provided the evidence for it to become the most consequential voucher in the history of herpetology. Fortunately, the combination of aberrant dorsal and unusual ventral color patterns in live-captured MCZ R-101991, compared to the typical patterns of each of the parental species, drew attention to the significance of the lizard (Neaves 1971). After studying his Fig.

1 and examining the specimen, we initially hypothesized that the unusual dorsal and ventral color patterns were phenotypic consequences of hybrid-derived tetraploidy per se. However, further analysis indicated that it is more likely that the unusual pattern of MCZ R-101991 resulted from a mating between a normally patterned *A. exsanguis* (Fig. 2R) and an aberrantly patterned *A. inornata* as represented by MCZ R-100080 (Fig. 1L). According to W. B. Neaves (pers. comm.), all of the F_1 hybrids generated by the whiptail lizard research group at Stowers Institute for Medical Research, Kansas City (see Lutes et al. 2011; Fig. 1 A and B), in the quest to synthesize hybrid-derived IRTPL have been parented by mothers (*A. exsanguis*; Fig. 2R) and fathers (*A. inornata*; Fig. 2L) with normal color patterns (also see Lutes et al. 2011; Fig 1A). This has resulted in both male and female F_1 hybrids, none of which possessed joined paravertebral stripes as seen in hybrid MCZ R-101991 (Fig. 2-M). Thus, should the potential for production of an *A. exsanguis* x *A. inornata* tetraploid parthenogenetic species be realized in nature, its discovery should not be expected to be based on aberrantly patterned lizards such as MCZ R-101991. Rather, its recognition would be triggered by subtle rather than striking color pattern distinctions from *A. exsanguis* (e.g., Lutes et al. 2011; Fig. A and B). Based on this study, we predict that it will be found that naturally occurring, as well as laboratory synthesized species of this hybrid combination, will closely resemble the maternal progenitor in color pattern (i.e., in having six faint stripes, profuse spotting, and muted contrast between these components and the ground colors). Moreover, we predict that the tetraploid species, as is also true of MCZ R-101991, will not be diagnostically different in either scutellation or meristic characters.

The unique significance of MCZ R-101991 to evolutionary biology is that it was foundational to the laboratory experiments leading to the laboratory synthesis of the first reported IRTPL. Based on the observation of Neaves (1971) that the hybrid female had oviposited putatively fertile eggs during captivity, Lutes et al. (2011), guided by W. B. Neaves some 40 years later, chose to pursue a course of experimentation using the same parental species that produced the possibly fertile lizard reported in 1971 ostensibly to synthesize one or more IRTPL. Indeed, they stunned the scientific community, and none more than us, with the report of the synthesis of three IRTPL descended from three tetraploid hybrids from the same clutch produced by one laboratory hybrid of *A. exsanguis* x *A. inornata* (Lutes et al. 2011). This achievement is all the more remarkable in light of the report of Cole et al. (2010) that they had no success in synthesizing either a triploid or a tertaploid hybrid-derived IRTPL in 29 years of experimentation using a variety of species.

Acknowledgments.—We are grateful to José Rosado, Harvard Museum of Comparative Zoology, for the loan of the specimens upon which this study was based, and for providing a digital image (Fig. 1). An anonymous reviewer provided helpful suggestion that led to reorganization of parts of the text. We also extend special appreciation to W. B. Neaves for encouragement, personally communicated information, and use of reproductions of an image made in 1967. Harry L. Taylor read the manuscript and recommended an important revision.

Preliminary Nocturnal Road Survey of Snakes in Northeastern Swaziland: Effects of Agriculture on Relative Abundance

Although the global biodiversity crisis has garnered much conservation attention for some vertebrate groups (e.g., mammals, birds, amphibians), declines of squamate reptiles are evident, but relatively poorly known (Gibbons et al. 2000; but see Sinervo et al. 2010). Population declines may be particularly prevalent in snakes (Reading et al. 2010); however, owing partly to their reclusive nature, studies documenting demographic patterns or shifts in community composition are relatively few (Dorcas and Willson 2009).

Here we report a preliminary survey documenting differences in snake assemblages between subtropical savanna (protected areas) and agricultural (sugarcane plantations) habitats in the Lowveld along a road transect in northeastern Swaziland (Fig. 1). In Swaziland, communal and protected lands occur as a fragmented matrix embedded within agricultural lands. Sugarcane production accounts for 59% of Swaziland's agricultural output, and the total area devoted to sugarcane monoculture has increased steadily over the past fifty years (Knox et al. 2010; USDA 2013). Habitat degradation is likely the primary contributor to snake declines (Dodd 1987), but the specific effects of sugarcane plantations on snake assemblages are poorly understood. Swaziland is densely populated, and is under increasing pressure to convert natural habitats to agriculture. As this conversion continues, information regarding its impacts on snake assemblages will be needed to inform management strategies for threatened species, such as the Southern African Rock Python (*Python natalensis*).

Materials and methods.—Our study area was located in the northeastern Lowveld region of Swaziland (Fig. 1). The Lowveld is characterized by subtropical climate, with annual rainfall of 550–725 mm, and a mean summer temperature of 26°C (Monadjem and Garcelon 2005). Our efforts were concentrated in the Hlane-Mlawula-Mbuluzi reserve network, the system of protected areas in Swaziland (Monadjem and Reside 2008). The reserve network is primarily savanna and dominant tree species include *Acacia nigrescens*, *A. tortilis*, *Dichrostachys cinerea*, *Ficus sycomorus*, and *Ziziphus mucronata* (Monadjem 2005). Characteristic grasses are *Cenchrus ciliaris*, *Digitaria eriantha*, *Panicum maximum*, *Themeda triandra*, and *Urochloa mossambicensis* (Boycott et al. 2007).

We designed a road transect for sampling snakes such that each complete round-trip circuit included equal distances in both protected areas and sugarcane plantations (Fig. 2). In total, our transect route included a 66-km stretch of MR3 with a portion of MR24 and an eight-km extension road, all of which is paved. Highway MR3 is a two lane highway that runs west–east from South Africa to Mozambique and has heavy traffic. Along this transect are Mbuluzi Game Reserve, Mlawula Nature Reserve, and Hlane Royal National Park, which constitute protected savanna habitat. MR3 bisects both sugarcane plantations and a game reserve, Hlane Royal National Park. MR24 traverses only sugarcane plantations, and the extension road off of MR3 passes through portions of both Mbuluzi Game Reserve and Mlawula Nature Reserve. Located along the transect are the small towns of Simunye, Maphiveni, Tabankulu, and Mhlume. The Simunye and Mhlume Estates are major sugarcane plantations along the study transect. In addition, the Mbuluzi River flows underneath a portion of MR3 and the Mlawula River flows parallel to the extension road near the Mlawula Nature Reserve.

We surveyed snakes along the road transect on most nights between 2 January and 12 February 2014, during the summer rainy season. The survey route was driven 1–3 times each night, depending on time constraints and snake activity; importantly, distance traversed in protected and agricultural areas was the same for each survey night. Each night we randomly chose the start direction to avoid biasing the beginning and end times for traversing particular habitats. Surveys were conducted between 1800–0100 h, with an average drive speed of 40 km/h. For each survey, we recorded date, start time, number of round-trip circuits, and end time. For each snake observation, we recorded genus and species, time, GPS coordinates, and condition (alive-on-road [AOR]; dead-on-road [DOR]). Dead snakes were removed from the road to avoid repeated counting, and some of those were preserved as voucher specimens (museum deposition information pending).

We compared relative abundances of snakes (all species combined) between savanna and sugarcane plantations by

calculating the number of snakes encountered per kilometer, a common metric used in snake road-survey studies (e.g., Mendelson and Jennings 1992; Sullivan 2000). We tested whether relative frequencies of individuals encountered at the family level (Pythonidae, Atractaspididae, Colubridae, Elapidae, and Viperidae; Table 1) were independent between habitat types using Pearson's chi-square test. We pooled observations into families rather than species because of overall low sample sizes across individual species. We included diurnal species in the analysis because we had no *a priori* reason to assume a bias between habitat types and we had no way to determine time of death for DOR snakes (i.e., diurnal species may be active at night depending on weather conditions).

Results and discussion.—We sampled 33 nights over a 42-day period, covering a total distance of 3234 km (1617 km in each habitat). Over the duration of the study, we observed 85 snakes representing 20 species and five families (collectively, 0.026 snakes per km). DOR snakes comprised 68% of all snakes observed (DOR = 0.018 snakes per km; AOR = 0.008 snakes per km); however, the proportion of DOR snakes is inflated by individuals of diurnal species found after sundown. Of all species encountered during surveys, only six were found in both habitats. The most frequently observed species, *Python natalensis*, was observed exclusively in protected areas, and made up 33% of all snakes encountered.

Snakes were encountered 3.5 times more frequently in protected areas than in agricultural habitats based on number of snakes observed per km (0.039 snakes per km for savanna, 0.011 snakes per km for sugarcane). Furthermore, snake assemblages, based on relative abundances of individuals recorded for each family, differed between protected and agricultural habitats (χ^2 = 22.625, d.f. = 4, P = 0.002). Differences in snake assemblages were driven largely by the dominance of pythons in protected areas and the higher than expected frequency of elapids in agricultural habitats. Observed and expected frequencies for each of the remaining families (Colubridae, Viperidae, and Atractaspididae) were similar between habitats.

Although roads may contribute to high levels of snake mortality (e.g., Rosen and Lowe 1994), they have also proven to be effective tools for surveying snake populations at regional scales (Mendelson and Jennings 1992; Sullivan 2000; Jones et al. 2011; McDonald 2012). In northeastern Swaziland, we found snake species richness to be similar between protected and agricultural areas (14 species in savanna vs. 12 species in sugarcane), but relative abundance overall was much higher in protected areas (Table 1). Taken together, our results were driven primarily by the dominance of pythons in the dataset, and their clear affinity for protected areas over agricultural areas. It is likely that pythons do not dominate the snake assemblage numerically, but are more visible on roads, and may remain on roads longer than other snakes. We attribute the high relative abundance of rock pythons in protected habitats to their specific requirements for refugia and nesting sites, which include large underground burrows

TABLE 1. Total number of snake observations in sugarcane and savanna habitats within the study area, northeastern Swaziland, from 2 January to 12 February 2014. Brackets indicate number of DOR snakes.

Family	Species	Sugarcane	Savanna
Pythonidae	*Python natalensis*		28[22]
Atractaspididae	*Amblyodipsas polylepis*		1

and cavities in termite mounds. These microhabitat features are largely absent from sugarcane plantations. Furthermore, sugarcane is harvested by first burning and then cutting to ground level, and it is unlikely that these large constrictors would survive this activity.

Our analysis at the family level indicated that the Elapidae (cobras and mambas) may be the only group of snakes that was relatively more abundant in sugarcane plantations (albeit sample size was small). These active, largely diurnal predators may maintain core home ranges in edge or more natural habitats while moving extensively through sugarcane plantations (see Phelps 2002). Alternatively, elapids may use available microhabitats in sugarcane more effectively than do other snakes, and may attain high densities due to competitive release from other species that are adversely affected by agricultural practices. Elapids are generalist predators that frequently take rodent prey, and agricultural areas in Swaziland sustain rodent densities equal to those in more natural habitats (Hurst et al. 2014), and may simultaneously harbor fewer predators of snakes. However, more extensive surveys will be needed to confirm the validity and generality of this potential trend in relative abundance.

Despite the many biases inherent in road-cruising studies and our low survey sample size (e.g., some species may use roads more frequently than others, some species may be more visible on roadways, activity times and microhabitats differ across species; see Sullivan 2012), our data suggest that agricultural habitats, and sugarcane monoculture in particular, have a negative impact on snake assemblages. Our preliminary study adds to previous research showing declines in squamate species associated with habitat alteration in southern Africa (e.g., Branch 1998; Meik et al. 2002; Gardner et al. 2007; Trimble and Aarde 2014) and provides additional evidence that anthropogenic habitat degradation may threaten snake populations globally (Dodd 1987; Dorcas and Willson 2009). In addition, we note that 22 out of 28 pythons encountered were DOR, indicating that automobile traffic may be a significant source of mortality for pythons. These snakes are large and slow-moving, and apparently use roads to thermoregulate. Population viability of snakes related to road mortality is a conservation concern that has been largely neglected (Rosen and Lowe 1994; Dorcas and Willson 2009) and may benefit from increased focus in southern Africa.

Acknowledgments.—We thank C. Taylor, B. Smith, J. Shapiro, H. Echecolonea, K. Howard, and P. Simelane, C. and T. Litschka-Koen for field assistance. We thank C. Higgins and T. LaDuc for discussion and comments on earlier drafts. Funding was provided by a Tarleton State University Student Research Grant and the Tarleton State University College of Agricultural and Environmental Sciences to JO, a grant from H. and L. Darley (Nancy Ruth Fund) to JMM, and a grant from the US Department of Agriculture – National Institute of Food and Agriculture to TWS. Collection and exportation of specimens was made possible by the generous assistance of A. Monadjem, University of Swaziland. Shelter, logistics, and hospitality were provided by All-Out-Africa, the Savannah Research Station, and Mbuluzi Game Reserve, especially T. Kaselowski and T. Fineberg, to whom we owe much gratitude.

Reptile Use of Trails in the Phoenix Mountain Parks

Urbanization can be a source of habitat removal and degradation threatening some species of herpetofauna (Gibbons et al. 2000; Wolf et al. 2013). Species richness for amphibians and reptiles often declines in areas of high urbanization from loss of suitable habitat (McKinney 2008). However, within urban areas where natural habitats are preserved or protected, herpetofauna often persist (Hamer and McDonnell 2012). The ability to monitor impacts from human interactions on these protected areas can be essential for effective management (Goode et al. 1995).

Protected areas juxtaposed with urban areas can be popular for outdoor recreation and offer many social benefits to city residents. However, outdoor recreation such as hiking, mountain biking, and horseback riding can have both direct and indirect effects on wildlife and their habitats. For example, trail use can directly affect small animals by trampling or by disturbing refuges or breeding sites (Knight and Cole 1995). Indirect effects can alter habitat by compacting soils, introducing weeds, causing erosion, reducing vegetation or ground cover, or cause behavioral responses in wildlife by eliciting a flight response (Cole and Landres 1995). To ensure viable populations and communities, a better understanding of these recreational disturbances on wildlife is crucial.

Studying relationships between reptile abundance and diversity with recreational trails can benefit park managers by providing data on how trail usage and habitat characteristics may affect herpetofauna communities. We compared the reptile community and their habitats along multiuse trails and at off-trail sites. Our research objectives were to investigate how reptile abundance and diversity and habitat characteristics varied in relation to trails. We predicted that locations further away from trails would contain greater reptile abundance and diversity due to less human interaction and habitat modification.

Methods.—For our study, we chose McDowell (33.6952°N, 111.7348°W) and Usery (33.4791°N, 111.6191°W) Mountain Regional Parks, located in the Phoenix Metropolitan Area, Arizona, USA. These parks offer a model system to evaluate the effects of recreational trail use on reptile species. The two parks offer miles of multiuse trails for recreational activities, represent a large variety of plants and animals, and are surrounded by urban development within the Upper Sonoran Desert.

We performed surveys at each park along different trail conditions (high-use and low-use) and types (trail and off-trail). To select high-use and low-use trails, we consulted with park managers to identify trails that were popular with recreationalists and other trails with relatively low visitation rates. In each park, we established 40, 10 m × 20 m plots (N = 80). Of the 40 plots, 10 were high-use plots, 10 were low-use plots, and 20 were off-trail plots. The location of the first plot along trails was randomly selected and subsequent plots placed every 150 m. We placed off-trail plots 150 m perpendicular to trail plots and side was determined randomly. We took care to make sure no off-trail transect interested with other recreation trails within a park and were > 150 m from any other trail.

We quantified reptile abundance and diversity using visual encounter survey methods (McDiarmid et al. 2011). Two trained observers surveyed each plot once in July and once in August 2013 during morning hours (0600–1100 h) when reptiles are most commonly active (Brennan and Holycross 2009). Surveys were area-constrained and we exhaustively searched each plot under suitable debris, logs, and rocks while disturbing vegetation. We recorded all reptile observations by age class (hatchling or adult), location, and species.

Using similar methods to Banville and Bateman (2012), we measured habitat characteristics for each of the 80 plots (Table 1). We quantified percent ground cover (i.e., bare ground, cryptobiotic crust, litter, and woody debris), vegetation cover (i.e., cactus, shrub, succulent, and tree), and burrow density at 10 square-meter intervals. The measured intervals consisted of 10 alternating square-meter sub-plots along a randomly chosen 20 m length of the plot. Using point-intercept methods, we quantified proportion of cacti, shrubs, succulents, trees, and woody debris (> 1 cm in diameter). We measured, at randomly selected quarter-plot intervals (5 m × 10 m), percent cover of boulder, cobble, gravel, and sand, and at randomly selected half-plot intervals (5 m × 20 m) we counted perennial plant species.

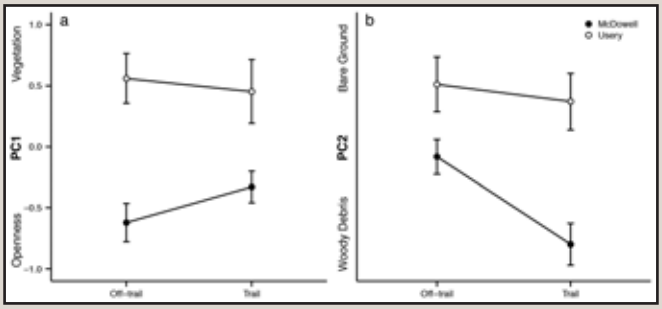

FIG. 1. Principle component factor values (PC1, PC2) depicting differences among park habitats in the Phoenix valley in central Arizona. PC1 values (a) are represented by the absence and presence of vegetation; cacti, shrubs, trees. PC2 values (b) are represented by the presence of woody debris and bare ground.

TABLE 2. Presence of lizards as predicted by habitat characteristics (component, PC) from logistic regression in mountain parks from central Arizona. *Callisaurus draconoides* was negatively associated with PC2 (high amount of bare ground, lacking litter and woody debris) and found around areas containing woody debris.

Species	Correlation (+–)	Component	Statistic	Significance (accuracy)
Aspidoscelis tigris	NA	NA	$\chi^2 = 1.271$	P = 0.260 (53.8%)
Callisaurus draconoides	–	PC2	$\chi^2 = 11.203$	P = 0.004 (80.0%)
Uta stansburiana	NA	NA	$\chi^2 = 1.413$	P = 0.234 (75.0%)

We defined abundance as the greatest number of individuals per age class of each species detected during both surveys in each plot. We compared reptile abundance between parks using the Mann-Whitney U test and quantified reptile diversity using the Shannon index. We used Principle Component Analysis (PCA) to reduce habitat variables and summarize variation within plots. To determine differences in habitat, we used a two-way ANOVA to compare scores derived from the PCA between parks and trail type. To evaluate species-habitat relationships, we used logistic regression to correlate species' occurrences with derived PCA component scores. All analyses were conducted using SPSS Statistics (IBM Corp. version 22.0).

Results.—We recorded a total of 205 reptile observations consisting of 10 species with a Shannon's diversity index of 1.144. Species recorded at both parks include *Aspidoscelis tigris* (Tiger Whiptail), *Callisaurus draconoides* (Zebra-tailed Lizard), *Sceloporus magister* (Desert Spiny Lizard), and *Uta stansburiana* (Common Side-blotched Lizard). Species recorded only at McDowell Mountain Park include *Coleonyx variegatus* (Western Banded Gecko) and *Gambelia wislizenii* (Long-nosed Leopard Lizard). Species recorded only at Usery Mountain Park include *Cophosaurus texanus* (Greater Earless Lizard), *Crotalus atrox* (Western Diamond-backed Rattlesnake), *Masticophis flagellum* (Coachwhip), and *Urosaurus ornatus* (Ornate Tree Lizard). *Uta stansburiana* was the most common species at both parks, followed by *A. tigris*, and *C. draconoides* (58%, 23%, and 9% of abundance, respectively). We found *C. draconoides* (U = 666, P = 0.069) and *U. stansburiana* (U = 636, P = 0.102) in marginally greater abundances at trail locations compared with off-trail. However, overall reptile abundance was similar between parks (U = 678, P = 0.231), trail condition (U = 175, P = 0.490), and trail type (U = 763, P = 0.716); therefore, data were pooled for species-habitat analyses.

From the 14 habitat variables (Table 1), we identified five principle components that explained over 70% of the variation (eigenvalues > 1; PCA) in habitat among plots. Plots with high PC1 scores had high vegetation cover, proportions of cacti, shrubs, succulents, and a richness of vegetation species; plots with high PC2 scores had bare ground and lacked litter and woody debris; plots with high PC3 scores had gravel and a high density of burrows; plots with high PC4 scores had a high proportion of trees; and plots with high PC5 scores had few areas with cryptobiotic crust. PC1 values differed between parks ($F_{(1, 76)} = 26.771$, $P < 0.001$), were similar on and off trail ($F_{(1, 76)} = 0.104$, $P = 0.748$), and had no significant park x trail interaction ($F_{(1, 76)} = 0.762$, $P = 0.386$). Usery Mountain Park had greater amounts of vegetation than McDowell Mountain Park (Fig. 1a). PC2 values differed between parks ($F_{(1, 76)} = 20.240$, $P < 0.001$) and between on and off-trail ($F_{(1, 76)} = 4.809$, $P = 0.031$), but had no significant park x trail interaction ($F_{(1, 76)} = 2.178$, $P = 0.144$). McDowell Mountain Park had greater amounts of woody debris than Usery Mountain Park, with most woody debris located along trails (Fig. 1b). PC3

values differed on and off-trail ($F_{(1, 76)}$ = 7.106, P = 0.009), with greater densities of burrows found off-trail.

Only the three most common species, representing 90% of abundance, were included in species-habitat analyses. Of the three species of lizards used in analyses, only *C. draconoides* had conclusive results. This species of lizard was negatively associated with PC2 (areas with high amount of bare ground, lacking litter and woody debris, Table 2).

Discussion.—Overall, we found that lizards did not avoid trails and some species may prefer areas with trails. For example, *C. draconoides* are known to occur in broad, sandy washes (Brennan and Holycross 2009), and this openness is imitated by the desert park trails. We observed twice as many *C. draconoides* at McDowell Mountain Park predominantly along trails where woody debris had been placed by managers. Lining trails with fallen trees and cacti was employed by park management to encourage users to stay on-trail. Modification of trails using woody debris may have contributed to habitat structure used by some lizard species. For example, we observed that *U. stansburiana* used the woody debris as perches. However, further study is needed to determine if reptiles utilizing trails are exposed to greater risks.

Some of the differences in habitat characteristic between the parks can be explained by a wildfire that burned McDowell Mountain Park in July 1995. Caused by lightning, this fire burned a large part of McDowell Mountain Park leaving areas void of large trees and cactus. This lower vegetation cover had no significant effects on reptile abundance and diversity between parks. However, the fire may be the source of woody debris that was placed along trails to keep recreationalists from going off-trail at McDowell Mountain Park (R. Hubbell, pers. comm. 2013); whereas, no woody debris was placed near trails at Usery Mountain Park.

Continuing to allow recreationalist an opportunity to enjoy county regional parks while protecting wildlife is a primary goal for park management (Taylor and Knight 2003). Our investigation of how reptiles respond to park trails allows greater insight for park managers. The research can contribute to effective management decisions for current and future parks. To support the conservation of wildlife and county regional park systems, we encourage further investigations of trails and possible impacts to biodiversity.

Acknowledgments.—We thank Dan Wilson, Brennan Basler, and Rand Hubbell for their logistical support and allowing us access to the Maricopa County Regional Parks. We thank the Central Arizona–Phoenix Long-Term Ecological Research (CAP LTER) for providing funding (NSF BCS-1026865). Special thanks to the Conservation Alliance, Justin Poulter for field assistance, and Kent Mosher for help with analysis interpretation.

Using Digital Photographs and Pattern Recognition to Identify Individual Boreal Toads (*Anaxyrus boreas boreas*)

Individual identification of animals can provide an array of useful capture-mark-recapture information, allowing researchers to estimate survival, movement, abundance, recruitment, and capture probability (Williams et al. 2002). This information can yield valuable insight to field investigators regarding a species' life history (Davis and Ovaska 2001; Phillott et al. 2007). Techniques used to identify individuals of many species have been developed and refined to gather this information. Toe clipping, PIT tagging, polymers and pigments, branding, and pattern mapping are all viable techniques for identifying individuals of many amphibian species (Donnelly et al. 1994; Davis and Ovaska 2001).

In addition to its potential utility in field investigations, individual identification is often important in captive populations. Knowing the identity of individuals allows accurate documentation of animal origin and breeding history, providing essential information when selecting individuals to breed in order to maintain a healthy, genetically diverse population. These goals are the impetus for the keeping of studbooks for a number of imperiled and critically endangered amphibian species. Individual identification capability may also facilitate the separation of brood stocks without the need to apply other marks.

Choosing the technique that best suits the species of interest as well as satisfying the questions at hand is important when determining how to identify individuals (Osbourn et al. 2011). In order to use pattern recognition as a capture-mark-recapture technique, the pattern on the animal should be distinguishable, remain stable, and be unique to the individual (Osbourn et al. 2011). These characteristics must be examined in any species for which pattern recognition is evaluated as a method. When not all of these pattern characteristics are present, false identifications may result (Kenyon et al. 2009). However, patterns that are unique and stable constitute the ideal mark because they cannot be lost, and concerns over deleterious marking effects that could affect results are minimized (Beausoleil et al. 2004).

In the past, pattern mapping has been a time consuming, demanding technique because an investigator had to either sketch the pattern of the specimen or wait to develop film (Donnelly et al. 1994; Plăiaşu et al. 2005), accompanied by the uncertainty over the quality of photographs taken. Recently, the affordability and quality of digital cameras have made pattern mapping more feasible. The ability to take, assess the quality, and retake a photograph while the specimen is still available makes pattern mapping and digital photography a suitable option (Bradfield 2004). Furthermore, digital photographs are less intrusive than PIT tagging or toe clipping; there are no wounds or potential infection sites created when taking a digital photo (Carafa and Biondi 2004; Plăiaşu et al. 2005). These advantages make digital photographs for individual identification appealing, especially when working with a state endangered species such as the Boreal Toad (*Anaxyrus boreas boreas*) in Colorado.

Colorado Parks and Wildlife (CPW) maintains a captive population of approximately 700 Boreal Toads at its Native Aquatic Species Restoration Facility (NASRF) for which unique identifications are necessary. Implanting captive toads with PIT tags seemed a logical choice given apparent high retention rates in wild toads (e.g., Scherer et al. 2008; Muths et al. 2010; Pilliod et al. 2010). However, long-term retention rates of PIT tags in our captive population have been much less than 50%, despite being implanted by the same individual who implanted PIT tags into the toads in the Muths et al. (2010) study (K. B. Rogers, pers. comm.). Hatchery toads were smaller on average than wild adult toads, so size at tagging may have had an effect. Whatever the cause of this excessive tag loss, it was clear that CPW would not be able to rely on PIT tags to identify individuals in this captive population. Toe clipping, although a generally reliable, inexpensive method to identify individuals, was deemed unsuitable for identifying the toads housed at NASRF because of the large number of toe removal combinations that would be required.

To find a more viable and reliable option, we explored phenotypic characteristics of the Boreal Toad. The Boreal Toad's ventral morphology consists of a cream-colored belly, creating a contrasting backdrop to the black markings on the belly. The

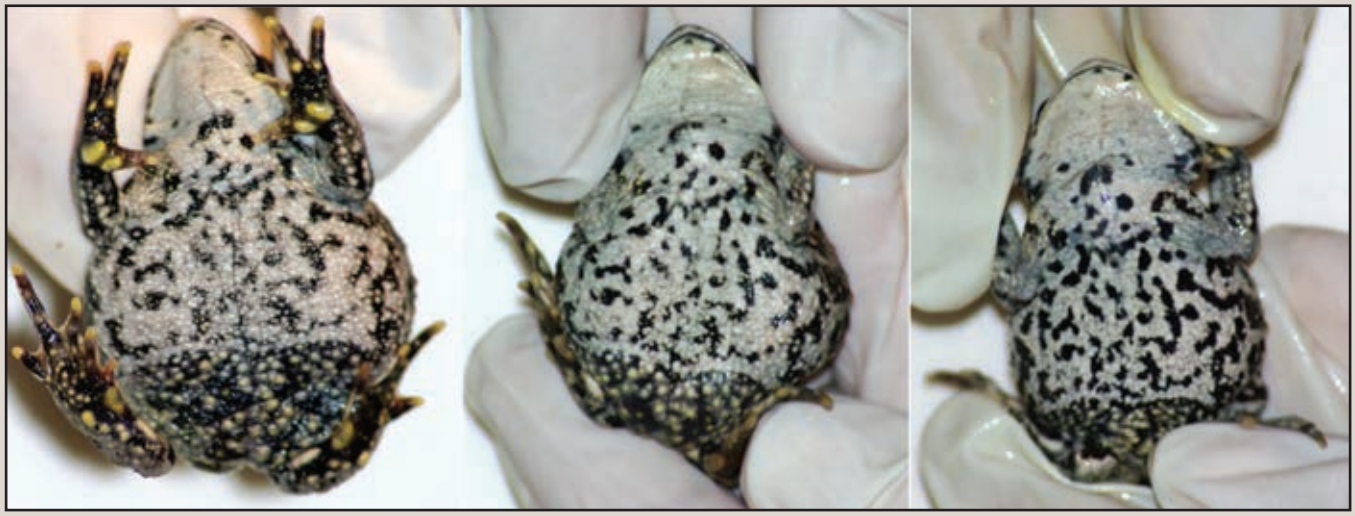

FIG. 1. Three photos taken of the same toad at the Cheyenne Mountain Zoo demonstrate pattern stability over 10 months representing the first year of life, in September 2007 (34 mm SVL, 4.2 g, left, age 2 months post-metamorphosis), February 2008 (44 mm SVL, 8.0 g, middle, age 7 months post-metamorphosis), and July 2008 (47 mm SVL, 9.2 g, right, 12 months post-metamorphosis).

resulting stark contrast makes the Boreal Toad a good candidate for pattern mapping. However, it was unknown if belly patterns remained unchanged as recent metamorphs or yearling toads mature to adults. Our goal was to assess the suitability of belly pattern recognition using photography as an alternative method to identify hatchery brood toads, and to ascertain whether Boreal Toad belly patterns are stable through growth and time.

METHODS

Cheyenne Mountain Zoo.—In August 2007, 38 Boreal Toads originating from a single clutch and aged about 1.5 months post metamorphosis were transferred from NASRF to Cheyenne Mountain Zoo (CMZ) in Colorado Springs, Colorado to assess the uniqueness and stability of the belly patterns as they aged and gained size. There, toads were randomly assigned to one of two rearing tanks (N = 19 each tank). They were photographed, measured (snout–vent length, mm) and weighed (g) initially on September 8 and each toad was assigned a unique identification number that was annotated onto the original digital photographs. These became the reference photographs. All toads were subsequently photographed once each month from October 2007 through February 2008, then in April and July 2008. Eighteen toads in each tank were implanted with PIT tags at the April 2008 photograph occasion, when average weight was 12.1 gm (SE = 0.51). Upon completion of each set of photographs, KZF matched new photographs with the reference set and labeled each of the new photographs accordingly, but maintained the base photograph number as a component of each photograph name. Matches were later evaluated and confirmed by AWN and KGT; thus, three investigators had to agree on each photograph match to be considered a successful match. This series of photographs provided a 10-month window to compare the belly patterns using original photographs against the seven follow-up photograph sets.

We tested whether investigators unfamiliar with the toads could successfully match photographs by asking ten people to match the reference September photos of the toads with one or more of the succeeding sets of photographs. Eight of the ten individuals worked with just one set of succeeding photographs, and two individuals matched reference photographs with two succeeding sets. All seven succeeding sets of photographs were matched against the reference set at least once. These individuals were provided annotated reference photographs, the follow-up candidate photographs they were assigned bearing only the file name generated by the camera, and a data sheet upon which to record candidate photograph numbers next to the individually identified reference photograph numbers. Six of the 10 had no previous toad experience. The individuals were informed what tank the toads belonged in, so we achieved twelve blind photo-matching opportunities on all toads from each tank. AWN and KGT assessed recording sheets for accuracy in identification by checking the base photograph numbers of candidate photos supplied to the ten individuals against the base photograph numbers of the appropriate follow up set of photographs that included individual toad identification.

Native Aquatic Species Restoration Facility.—We initiated the use of belly pattern photographs as the primary method to identify individuals at NASRF in 2007. The toads were housed in tanks and separated into "lots," which usually consisted of 10–15 sibling toads. Over 700 toads ranging from age 1 to age 8, as well as some toads brought in as unknown age adults from the wild prior to the year 2000, were photographed in 2007. In subsequent years the additions to the population were photographed at about age 1, or after their first hibernation. Each toad was assigned a unique ID incorporating its lot number at the time its photograph was taken. The belly pattern photographs were copied to a Powerpoint presentation and arranged by lots with up to six thumbnail photographs per page along with each toad's unique ID added below its photo. The thumbnail pages were printed and laminated to protect and extend the life of the photographs.

The availability of captive toads at NASRF provided the opportunity to further investigate the stability of belly patterns. In 2009 we photographed five lots of yearling toads twice, in March and November. The lots ranged in number from three to 15 toads, and comprised a total of 29 animals. The photographs were then matched between the March and November occasions within each lot to evaluate stability of pattern over eight months during a period of rapid growth. Consensus on general spot pattern and three or more specific match points (e.g., uniquely

FIG. 2. Series of photographs taken at NASRF of two individuals demonstrate pattern stability throughout multiple years of growth. Photographs on the left were taken in September 2009 (average weight 2.5 g, age 13 months post-metamorphosis), middle in March 2010 (average weight 23.8 g, age 19 months post-metamorphosis), and the right in August 2012 (average weight 59.5 g, age 4 years post-metamorphosis).

shaped spots or placement of spots in relations to others) for March and November photographs among three investigators was considered a successful match. We also periodically photographed the bellies of two toads brought into captivity from the wild as they matured from age 1 to age 4, when Boreal Toads generally reach adult size. These animals were housed together, but without other animals, in the display tank at NASRF. At the end of our study the serial photographs of the two display toads were compared both among the photographs taken and with the live toads. Again, consensus on general spot pattern match and three or more specific match points among serial photographs on the part of three investigators was considered a successful match. These trials allowed us to extend observations of belly pattern stability to a longer time period and greater growth difference than we were able to achieve at CMZ.

We also conducted a timed toad identification experiment in 2012 to investigate the efficiency of using belly pattern photographs to ID toads. At NASRF, three separate toad lots were selected for the study; one lot contained 15 animals and the other two lots contained 14 animals each. Each toad lot was assigned to four investigators with varying levels of familiarity using photographs to identify individual toads. The investigators were ranked into three categories: novice, experienced, and expert. "Novice" was defined as having no experience using photographs to ID toads, "experienced" as having used photographs previously for toad ID but not on a regular basis, and "expert" as having used photographs frequently to ID toads, either at NASRF or during field studies in 2009–2012. An investigator compared a toad in hand to the previously described photographs of the lot, which were placed on a counter so that photographs of all toads in the lot were visible at once. As toads were presumptively identified, the investigator placed each into a numbered container corresponding to the last two digits of the unique ID. Once all toads from a lot were identified and in containers, two other investigators verified that the identifications were correct by examining each toad's belly and the photograph it was matched with. Consensus on the general spot pattern and three or more specific match points was considered confirmation of the original identification. Timing commenced when the identifying investigator picked up the first toad and ceased when

the last toad was placed into a container, and did not include the verification procedure. Time to individually identify toads and the accuracy of identifications was compared among categories of investigators using the single factor ANOVA procedure in the statistical software MINITAB (version 14.1, Minitab Inc., 2003).

Results

Cheyenne Mountain Zoo.—Average size of toads on 8 September 2007 was 32.7 mm SVL (SE = 0.36) and 3.5 g (SE = 0.12), the average size of the toads at the end of the study on 17 July 2008 was 52.2 mm SVL (SE = 0.82) and 10.9 g (SE = 0.48). One toad died prior to the April and July photographs. The photographs from each of these months were used once in the matching exercise, so a total of 454 matching opportunities were achieved rather than the 456 possible had all toads survived (12 matching exercises x 38 toads).

Investigators correctly matched 449 photograph pairs in 454 opportunities resulting in 98.9% success. Nine out of the 12 blind tests achieved 100% success matching the reference toad photographs to photographs from one to 10 months later (the final photographs taken, Fig. 1). Three errors were encountered during the study. One experienced investigator transposed two toad identification numbers on the recording sheet, but this was a recording error and not a misidentification resulting from similar patterns. A novice investigator assigned a single follow-up photograph to two different toad reference photographs (one was correct) resulting in misidentification of a single toad. The last error occurred when a novice investigator misidentified a pair of toads. Thus there were three true cases of mistaken identity in 454 opportunities (99.3% success). Clearly, belly patterns are distinguishable even to people who are unfamiliar with Boreal Toads and identification performance may improve with increasing familiarity with the photography system.

The PIT tags implanted in April were poorly retained. By week 9 post-implantation, retention was just 44% in each tank. At the July photography occasion, 13 weeks post-implantation, only four PIT tags remained implanted, with 16.7% retained in one of the toad tanks and 5.6% retained in the other.

Native Aquatic Species Restoration Facility.—Among the five lots of yearling toads photographed twice in 2009, all March photographs were matched successfully to November photographs, and both photograph sets were matched successfully to live toads. In no instance was there disagreement among three investigators over matches. These comparisons were limited to within lots, so there were no opportunities to misidentify toads to different lots.

Over the three-year period using serial photographs of two Boreal Toads held in the display tank at NASRF, the belly patterns of both the subject animals remained stable and identifiable as the toads matured from age 1 to age 4 and increased in mass from 2.5 g average to 59.5 g average (Fig. 2). Even over a three-year period, in no instance was there disagreement between two investigators over the identity of these two toads when assessing general spot pattern as well as multiple specific match points.

Twelve timed ID trials were conducted to identify the toads (three toad lots, with four investigators per lot). Only one investigator (from the category "experienced") failed to achieve 100% correct identification, and all errors occurred within a single lot of toads. One hundred sixty-nine of 172 (98.3%) toad identifications were correct. Single factor ANOVA indicated that investigator experience was not a significant predictor of the time required to sort a lot of toads into individual containers ($F = 1.87$, $df = 2, 9$, $P = 0.209$) or of accuracy in doing so ($F = 1.00$, $df = 2, 9$, $P = 0.405$). Two lots were judged as being easy to identify because of the large, distinct blotches characterizing these animals, whereas the third lot was more difficult to identify because the bellies were characterized more by freckling than distinct blotches. The time required to sort all the toads into individual containers averaged 9.5 minutes (SE = 0.7) for the easy lots and 17.5 minutes (SE = 3.6) for the more difficult lot.

Discussion

Our results supported the use of belly pattern photographs as a viable method to identify individual Boreal Toads. The belly patterns exhibited a high degree of stability, fully sufficient to remain effective for identification over considerable growth and time intervals even when slight changes to pigment density were apparent (e.g., Fig. 2). While we did not use a secondary method of identification in these studies, we found that it was generally easy to reach consensus among investigators when comparing photographs to other photographs or to live toads. Only in rare instances did we have to resort to discussions of specific match points to confirm identifications or to determine a misidentification. The fact that our toads were housed in discrete tanks containing a known number of toads worked to our advantage. There is a possibility that additional error could occur if unknown toads had been introduced to tanks, or if additional photographs of animals not present in the tanks were available. However, staff at NASRF already encounter the latter situation when replacing breeding animals into their assigned tanks after breeding. In such cases the photographs for at least two lots must be used to discriminate the toads and place them where they belong.

Observations of toads over time at CMZ and NASRF strongly suggest there is little likelihood of false identifications of Boreal Toads resulting from changing patterns as observed in other species (Kenyon et al. 2009; Waye 2013). The chance of error is further reduced if the need for individual identification is limited to one or two lots of toads. If false identifications occur, we think it more likely to occur as a result of similar belly patterns. We are aware of just one instance of such a false identification at NASRF, when an animal sent to another institution was identified as a different animal from the same lot (siblings). The mistake was later discovered and corrected. A precaution against such mishaps is the constant participation of a second observer to confirm putative identifications.

Attempts to identify individuals in other amphibian species via pattern recognition work well with species exhibiting distinct blotching that contrast boldly with the body, such as Marbled Salamanders *Ambystoma opacum* (Gamble et al. 2008), Yellow-bellied Toads *Bombina variegata* (Plăiaşu et al. 2005), and Fire Salamanders *Salamandra salamandra* (Carafa and Biondi 2004). Such species compare favorably with the Boreal Toad in pattern distinctiveness and contrast. Among these investigators only Carafa and Biondi (2004) observed changes in pattern over time, and those were slight enough that they did not preclude identification. However, in at least one other boldly marked species, Tiger Salamanders *Ambystoma tigrinum,* marking patterns have been observed to undergo significant changes over time (Waye 2013). We observed no such dramatic changes in the spot patterns of Boreal Toads, despite using many more than the 11 animals observed in the Waye (2013) study. Rather, our

results were more like those of Gollmann and Gollmann (2011), who found that although the patterns of early Yellow-bellied Toad metamorphs changed and solidified with growth, they could still identify individual toads.

The stability of the belly pattern in Boreal Toads over considerable growth is similar to that observed in the Yellow-bellied Toad as well. Plăiaşu et al. (2005) were able to photographically identify individuals that transitioned from subadult to adult stages, with associated weight changes. This stability may provide advantages to those conducting long term studies of Boreal Toad populations by allowing entry of individuals into the marked population at a younger age and smaller size than is presently possible, provided our results could be replicated in field situations when new, previously unknown toads were successfully identified as such. Scherff-Norris et al. (2002) recommended PIT tagging Boreal Toads that weigh a minimum of 10 g, and other investigators have limited PIT tagging to adult-sized Boreal Toads (> 55 mm SVL, Young et al. 2007). Many investigators have not reported minimum sizes tagged, but their primary tagging periods are during and just after breeding seasons so it is likely that tagged toads are predominantly adults (Scherer et al. 2005, 2008; Muths et al. 2006, 2010; Pilliod et al. 2010). In contrast, photographic identification may allow the entry of toads into the marked population as small as 2 g, as in our trial with the two wild-caught toads. This earlier entry into the marked population could be realized even if investigators ultimately wish to use PIT tags on older animals for the benefit of the quicker in-the-field identification.

Another benefit of photographic identification of Boreal Toads would be as an ideal second mark to evaluate the loss of other marks or tags. Despite the widespread and apparently successful use of PIT tags in Boreal Toad field studies, we could find no published evidence of a formal evaluation of PIT tag retention in wild Boreal Toads. That retention is much higher in wild toads than in our captive toads when PIT tags were implanted by skilled individuals is evident, because studies using PIT tags have produced modeled annual apparent survival rates of 0.75 or more (Scherer et al. 2005; Muths et al. 2010; Pilliod et al. 2010). However, Scherer et al. (2005) investigated models that evaluated tagging effects, and indeed tagging effects had support in their data and were included in all top-ranked models. Modeled apparent survival was commonly about 0.20 lower for toads in the first year after tagging than in subsequent years. A follow-up investigation that included a new study area also produced one model ranked among the top three that included a first-year tagging effect for the new study area (Muths et al. 2006). Unfortunately, deleterious effects of tagging that may have caused mortality could not be separated from the effects of potential short-term tag loss in these studies. A second mark allows the separation of tag loss from tagging effects or other factors affecting survival. We believe a study formally evaluating PIT tag retention in Boreal Toads could be achieved by the pairing of PIT tagging with photographic identification.

Acknowledgments.—A special thanks to R. Black, E. Davinroy, K. Duckett, C. Gesink, B. Groenke, N. Heredia, B. Nehring, C. Nilson, A. Petry, S. Rodman, T. Root, S. Sherman, and D. Westerman for participating in the photograph study. Comments received from S. Amburgey, L. Bailey, members of the Bailey Lab, M. Benard, and one anonymous reviewer greatly improved the manuscript. All toads were handled under the corresponding author's scientific collection permit, and all applicable institutional animal care guidelines were followed during the implementation of this project.

Use of an Exemplar Versus Use of a Sample for Calculating Summary Metrics of Morphological Traits in Comparative Studies of *Anolis* Lizards

Comparative morphological analyses of large groups of species are limited by the time needed to perform multiple measurements on several individuals of each studied species. For example, taking complete external morphological data (e.g., Poe 2004) for an individual *Anolis* lizard for phylogenetic analysis takes us approximately 14 minutes. If even five individuals per species are scored for every species in the *Anolis* clade, and we estimate 400 species of *Anolis*, data collection will take over 466 hours. But is it necessary to score lots of specimens to ascertain an informative summary of the population/species? Although more data are nearly always better, researchers must optimize the time spent on data collection relative to the goals of a planned study. If measuring one specimen achieves the same results as measuring (e.g.) five specimens, then measuring one specimen is preferable.

We investigated the efficacy of a time-saving approach for performing comparative morphological analyses of lizard species. In particular, we asked whether use of a single exemplar specimen—the largest male—provides distinguishable results from using means for five conspecific male specimens in some comparative species analyses of traits commonly employed in morphological, ecological, and phylogenetic analyses. We tested for sampling effects related to the number of individuals scored for five commonly used morphological traits and three commonly employed quantitative techniques (e.g., some traits and techniques in Losos et al. 1998; Poe 2004; Latella et al. 2011) in 15 species of *Anolis* lizards.

Five morphological characters for five adult males each of 15 species of *Anolis* lizard were collected using specimens from the Poe Lab and the Museum of Southwestern Biology at the University of New Mexico. The five largest adult males available to us for each species were used without concern for geographic origin. The following characters were collected according to procedures established by Williams et al. (1995) and Poe and Yañez-Miranda (2008): body size measured as snout-vent length (SVL) from tip of snout to anterior edge of cloaca; head length (HL) measured from tip of snout to anterior edge of ear opening; femoral length (FL) measured from the midline of the body laterally to the knee; scales across snout (SNSC) counted between second canthals; and lamellae count on phalanges ii and iii of the fourth toe of the hind foot (see above cited papers for more detailed character descriptions). Measurements were taken with digital calipers to the nearest 0.1 mm.

We performed analyses of species using two sets of these data: means for each species using all measured individuals, and values for the single largest male specimen for each species. We compared summary metrics for these two data sets for three techniques: 1) relationship of traits to body size (SVL vs. HL, FL, and lamellae; slope, R^2); 2) phylogenetic gap-coding (SNSC, SVL; Thiele 1993), a method that converts measurement data to phylogenetic codes; and 3) principal components (scores for PCI and PCII using all five variables).

Results are summarized in Table 1 and Figs. 1 and 2. We found that use of a single exemplar specimen per species produced

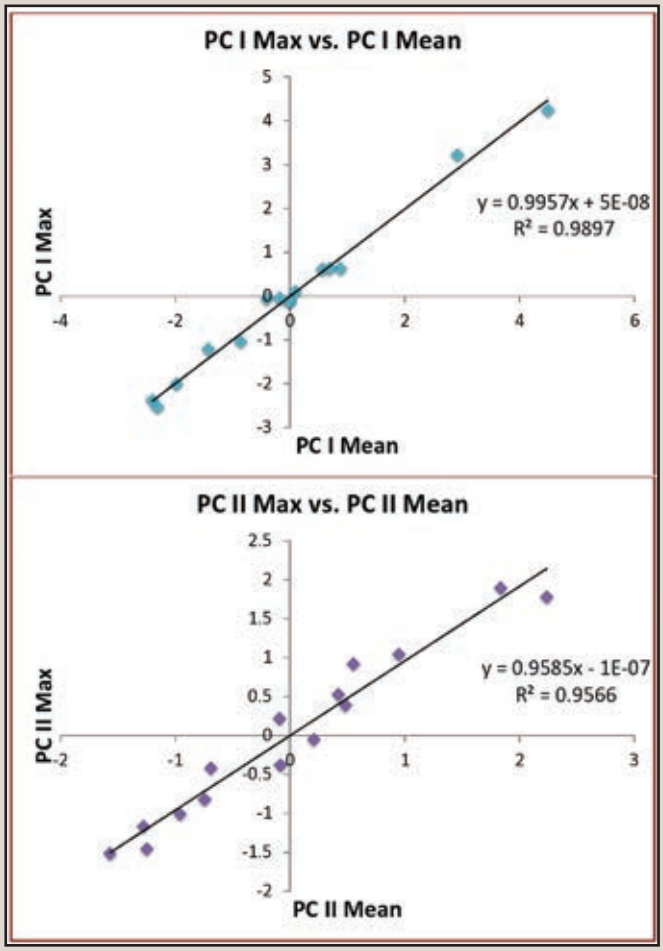

FIG. 2. Comparison of principal component scores.

nearly identical results to using summary statistics from five specimens for body size-trait relationships, phylogenetic coding, and principal component scores. Body size-trait relationships differ by less than 0.005 in slope, and by less than 0.008 in R^2 (Fig. 1). This similarity among datasets occurred both in traits expected to closely track body size (HL, FL) and in a trait known to correlate more weakly with body size (lamellae). The average difference between phylogenetic codes for each dataset was 0.4 on a scale of 0.0 to 5.0 for SVL and SNSC, and 19 of 30 codes were identical between the datasets (Table 1). Principal component scores were very strongly correlated between datasets (Fig. 2).

These results suggest that little would be gained by measuring five specimens rather than one specimen for these analyses (body size-trait relationships; phylogenetic coding; PC scores) for these traits in these *Anolis* species. A five-fold decrease in data collection time is not trivial in comparative studies of large clades. In the case of *Anolis*, the time saved by measuring one specimen rather than five would be on the scale of months, rather than hours. We conclude that some comparative interspecific morphological studies of lizards such as *Anolis* may proceed more efficiently by measurement of a single exemplar per species rather than multiple individuals.

Although results are conclusive for the traits, methods, species, and scale studied here, we do not recommend general extrapolation to other studies. There certainly are studies of morphology—perhaps most studies—wherein measurement of several or even hundreds of individuals per species or population is warranted. Studies of intraspecific variation, of growth within species, and of traits with high variance are obvious examples where many individuals must be measured in order to gain biologically meaningful results. Other cases similar to our study (e.g., interspecific principal component analyses) may produce similar results—i.e., adequacy of use of a single exemplar for some quantitative summary metrics. But these inferences are best made on a case-by-case basis. We believe that the null expectation for a study with unknown variance properties should be that measurement of more than one individual per species/population is warranted. A conservative implication of our results is simply that large sample sizes should not be assumed to be necessary for all studies.

A New System For Marking Hatchling Turtles Using Visible Implant Elastomer

Turtles are a particularly vulnerable taxonomic group, with 40% of all species currently placed on the IUCN Red List (van Dijk et al. 2014). Many recent conservation efforts for turtles focus on the long-term viability of turtle populations, particularly in light of habitat fragmentation, over-collecting, road mortality, and other anthropogenic stressors (Doak et al. 1994; Heppell 1998; Gibbs and Shriver 2002; Shoemaker et al. 2013). However, to determine long-term population viability, information must be collected on the demography of the target organism, including survivorship of juveniles (Shaffer 1981; Boyce 1992; Akçakaya and Sjögren-Gulve 2000). Mark-recapture methods are well-suited for studies of hatchling survivorship and ecology (Morafka 1994; Heppell 1998). However, many marking techniques for turtles, such as notching, drilling, and branding, may not be practical for use with hatchling turtles since a) the marks may not remain visible as the organism grows, and b) the marking process itself could harm animals of such small sizes (Plummer 1979; Davy et al. 2010).

Davy et al. (2010) recently proposed the use of Visible Implant Elastomer to mark small or hatchling turtles; however, their suggested marking systems do not allow easy identification of individual turtles and focus primarily on designating cohort marks for groups of hatchlings. Here, we present an intuitive, inexpensive, and easily recognizable individual marking system using Visible Implant Elastomer.

Methods.—Visible Implant Elastomer (VIE), available from Northwest Marine Technology, Inc. (Shaw Island, Washington, USA), is a tagging agent that has successfully been used to mark fish and amphibians (Bailey et al. 1998; Bailey 2004; Butt and Lowe 2007; Hutchens et al. 2008). VIE is a bio-compatible material that leaves a well-defined pigment mark that fluoresces under UV light. VIE consists of a two-part system: a colored component and a curing agent. After the two components are mixed, the elastomer is injected into an area of translucent tissue (Fig. 1A), creating a long, distinctive mark (Fig. 1B). If necessary, a small amount of liquid bandage can be applied over the injection site to further ensure that the cured mark is not lost. The Northwest Marine Technology, Inc. (2008) VIE injection manual describes complete VIE application methods.

Hatchlings of two species of turtles, the Northern Map Turtle (*Graptemys geographica*) and the Bog Turtle (*Glyptemys muhlenbergii*), were collected to test our marking system. All hatchling map turtles were either collected emerging from nest sites on the shores of the Susquehanna River in Maryland or were hand-captured basking or swimming in the river. As Northern Map Turtles overwinter in nests (Ernst and Lovich 2009), all new captures occurred in the months of May and June. Observed hatchling characteristics (i.e., presence of yolk scar and/or egg tooth) strongly suggest that all newly captured hatchlings were freshly emerged from nests during this period. Captured turtles were taken to a nearby field station for measuring and marking. Hatchlings were released within 24 h of marking to allow the elastomer to cure completely. All hatchling Bog Turtles were captured at sites in Maryland (specific site locations withheld for security reasons) emerging from nests in August 2013. Hatchling Bog Turtles were taken from the field for measuring and marking and released within 24 h of capture.

Previous VIE methods used in turtle research have involved injecting the elastomer material into the animal's limbs in various combinations of colors or locations (Park et al. 2007; Davy et al. 2010). Davy et al. (2010) also proposed applying these marks to the pliable plastrons of hatchling turtles. We expanded on this method by adapting the Ernst et al. (1974) marking system to fit the plastron of the turtle, giving each hatchling an individual mark number (Fig. 2). Rather than begin the numbering at the gular scutes, we began at the larger anal scutes and moved up the shell in order to make marking small turtles easier.

Results.—A total of 101 hatchling Northern Map Turtles were marked using VIE between 9 May 2012 and 29 August 2013. Twenty-one individuals were recaptured at least once, and four individuals were recaptured two or more times (Table 1). No juveniles marked in 2012 were recaptured in 2013. The marking scheme was also successfully applied to five hatchling Bog Turtles in August 2013 to test the utility of this marking scheme for another species.

A single *Graptemys geographica* hatchling marked in the 2012 field season was recaptured three times between the months of May and July of that year. When captured on 25 July 2012, the plastral VIE marks had faded somewhat but were still visible to the naked eye. The marks were easily recognizable under UV light. This individual increased in mass and straight-line carapace length from 7.4 g and 33.9 mm on 9 May 2012, to 42.0 g 66.3 mm on 25 July 2012. This equates to a 568% increase in mass and a 95% increase in shell length in 77 days. This is also the only individual in this study recaptured more than two months after marking, as most individuals were either not recaptured at all or were recaptured once within one month of marking.

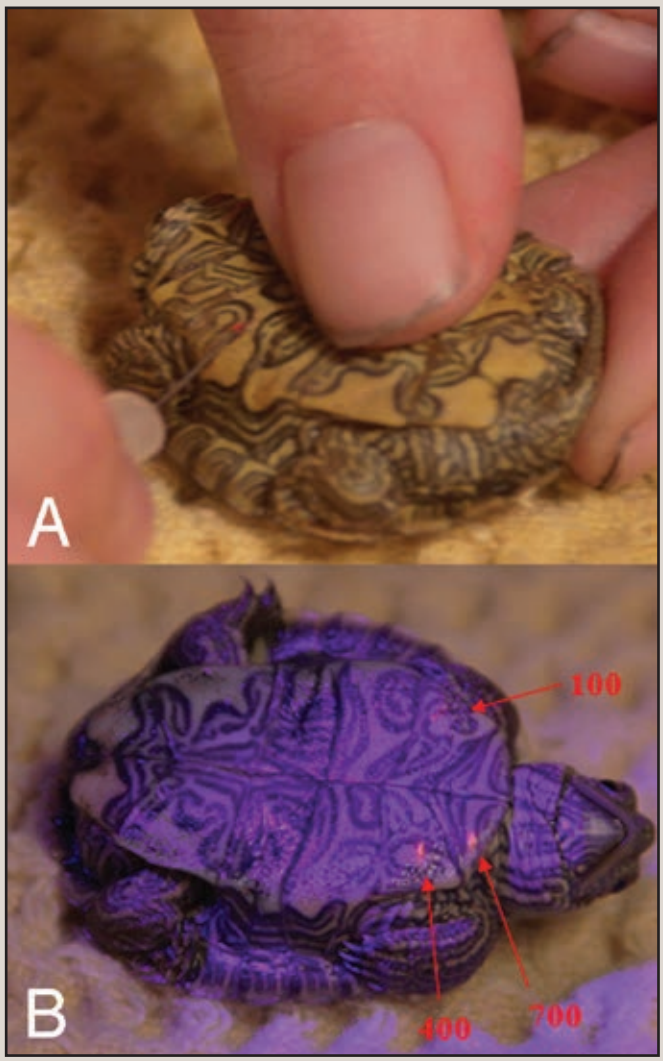

FIG. 1. A) Injection of visible implant elastomer into the plastron. B) Visible implant elastomer tag fluorescing under UV light for hatchling #1200. The dye on the chin is non-injected residual elastomer from the marking process, which quickly fades, leaving only the injection sites marked.

FIG. 2. Adaptation of the Ernst et al. (1974) system for marking turtles. Numbering begins at the bottom of the plastron rather than the top due to scute size.

TABLE 1. Individual hatchling marks and recaptures for 2012 and 2013.

	Marks/season	Recaptures	Repeated recaptures
2012	29	5	2
2013	72	16	2
Total captures	101	21	4

Discussion.—This method is a simple, inexpensive, and quantitative method for marking individual hatchling turtles. The elastomer material is effective for marking small or extremely large cohorts, yet maintains individual identification regardless of the cohort size. Our adaptation of the Ernst et al. (1974) system allows for a large number of individual mark numbers. The highest mark numbers reach into the 1400s for one color of elastomer; however, Northwest Marine Technology, Inc. offers six different fluorescent colors. Once the maximum number has been reached for one color, one can begin at mark #1 with a new color, or introduce combinations of colors.

The Ernst et al. (1974) marking system is a well-established marking scheme, making the numbering used in this marking scheme simple and familiar. Davy et al. (2010) reported that VIE marks may break apart, forming what look like multiple marks. Because the plastral marks are applied to separate scutes in our method, confusion over individual identification is avoided even if the elastomer breaks or changes shape. The VIE kit for this project cost about US $0.80/individual turtle. Costs for using PIT tags are generally no less than US $1–US 2/individual, plus $800–1500 for the PIT tag reader (Smyth and Nebel 2013). Therefore, VIE may represent a more cost-effective marking method than PIT tagging.

No hatchlings from 2012 were recaptured in 2013; the lack of data on captures between years limits any conclusions that can be made about the maximum lifespan of plastral VIE marks. However, Davy et al. (2010) reported at the time of publication that marks lasted at least until the next season. Recapture data from the present study suggest that marks can be retained in plastral scutes even with high rates of individual growth; however, conclusive long-term mark retention and visibility estimates should be a priority for future studies. Additionally, alphanumeric tagging, e.g., as applied by Strain et al. (2013), may represent another potential injectable marking system that could hold merit for hatchling mark-recapture studies. Since our system incorporates the Ernst et al. (1974) marking system, our marking system could easily be adapted to other types of injectable marking tools for hatchlings. Thus, this system represents an intuitive and easy-to-use alternative to currently existing hatchling marking techniques that, due to its flexibility, could easily be adapted to most studies of hatchling turtles.

Acknowledgments.—We are grateful to the townspeople of Port Deposit, Maryland, for serving as citizen scientists on this project

and for the use of their facilities as lab space. We thank N. Eller, K. Kolenda, and B. Seigel for their help with field research and E. Dallalio for referring us to Northwest Marine Technology, Inc. Funding was provided by Exelon Corporation, the State Highway Administration of Maryland, and Towson University. This study was approved by the Towson University Animal Care and Use Committee (permit FR#021913 RS-04) and the Maryland Department of Natural Resources (permit# 53939). Thanks to R. Seigel for providing comments on the manuscript and for assisting in obtaining funding for this project.

Data derived from the dissection of preserved specimens in herpetological collections have contributed immensely to our understanding of the biology of snakes (e.g., Fitch 1940; Allen and Neill 1957; Hoge and Romano-Hoge 1978; Diller and Wallace 1984; Salomão et al. 1995; Almeida-Santos and Salomão 2002; Pizzatto et al. 2007; Marques 2011; Barros et al. 2012; Rojas et al. 2013). Some museums contain historical specimens that have incalculable value; deciding whether to grant permission to dissect such specimens is a challenge for curators. Regardless of age, many specimens require special care such as when the specimens are damaged prior to collection (such as in roadkills), where body parts are sprawled, or when tissues have been manipulated during prior dissection (e.g., stomach contents, developing follicles, embryos, or eggs). As such, previously dissected specimens that have not been sutured may disrupt future data collection of anatomic features.

Despite such a long history of using preserved specimens for scientific study, little attention has been paid to the best ways

FIG. 1. Specimens dissected: longitudinal incision in which the ventral scales are divided into two relatively equal halves (A). The suture is anchored under the epidermal layer on the right side of the animal between two ventral scales (B). Begin the whip stitch by tying a knot in the end of your thread and alternatively the needle is placed from outside to inside with one bite then going from inside to outside on the next bite (C, D). The suture in the skin of the snake represents a simple continuous pattern or whip stitch (E). The muscular layer and subcutaneous layer are incorporated in the suture and the distance from one point to another is 5–10 mm. The needle used to close the incision was a straight surgical needle with taper point, size 2-3. Kite string was used to suture which when completed, is imperceptible to the naked eye (F). Li: longitudinal incision L: left; R: right; SS: scale space; Ssc: simple suture continues; f: fixation (anchor) point.

to minimize damage to specimens. The focus of this paper is to present a simple method of closing and securing dissected coelomic cavities of snakes that minimizes damage of the specimens in scientific collections.

After dissection (Fig. 1A), a continuous suture is initiated to close the coelomic cavity, by anchoring the suture on one side of the skin (Fig. 1B–D). This suture is characterized by a simple continuous pattern or whip stitch commonly used in medicine (Fig. 1E). In individuals that have been run over or in which the organs were collected from other sources, the pleuroperitoneal cavity is usually fragmented. This disruption causes the drying of tissues, making them fragile. It is important to note that the point of suture is not visible to the naked eye, which provides an aesthetic benefit, and avoids disruption of scale orientation (Fig. 1F).

With the adoption of this technique, researchers can obtain valuable information from specimens of varying condition while minimizing damage and prolonging their usefulness in collections. Scientific collections that do not allow or have restricted access to the dissection of specimens could consider this technique as a model for the upkeep of specimens that might be dissected in the future.

Acknowledgments.—We thank Guarino R. Colli for suggestions to improve the technique, Eduarda Salomon for help in obtaining rattlesnake photographs, and Paul Reynolds for the English review of the manuscript.

Using Transillumination as a Technique for Blood Sampling in Small Anurans

Obtaining blood samples is vital to many physiological and immunological studies. However the ease of sampling diminishes as the size of the animal decreases while the potential for harming the study organism increases. This is especially true in amphibians where reproductive adults can be as small as 2 cm and thin skin is prone to tear. Normal venous blood collection techniques for anurans include collection from the ventral abdominal, femoral, or sublingual vein (Hadfield and Whitaker 2005). Cardiocentesis is also a common collection technique particularly for smaller anurans due to small vessel size (Allender and Fry 2008). This technique is performed by inserting a syringe equipped with a hypodermic needle directly into the ventricle of the heart (Brazaitis and Watanabe 1982). Cardiocentesis protocols commonly suggest anesthesia to prevent additional damage to the heart or internal organs (Allender and Fry 2008). However, in most amphibians anesthesia can be precarious due to their sensitivity to anesthetics (Koustubhan et al. 2013) and it can interfere with many physiological measures that may be of interest (Houston et al. 1971; Cathers et al. 1997). If anesthesia is not an option, manual restraint must be used in conjunction with cardiocentesis. Small anurans are notoriously difficult to handle and because the heart presents such a very small target, it is easy to miss and puncture neighboring organs causing more damage than necessary and perhaps mortality. Restraint of smaller subjects without the aid of anesthesia is a difficult task and can cause injury in and of itself. For these reasons, investigators are faced with the challenge of creating a new technique that allows for more accurate location of the heart and less stressful restraint for smaller subjects.

Several techniques have already been established for visualization of internal structures in small subjects. Transillumination, or candling, has long been used to visualize internal structures of fertilized avian eggs and has recently been used to determine the sex of salamanders; a light passed through the abdomen allows for the visualization of the sex organs (Gillette and Peterson 2001). Transillumination is also used to view vessels in limbs of newborn infants to ensure blood collection on the first attempt (Wall and Kuhns 1977). In each of these studies, the use of a light source allowed the investigator to visualize vessels and organs using noninvasive techniques. We are proposing a novel use of transillumination in conjunction with a novel restraint technique to view the heart of small amphibians and to safely obtain a blood sample.

Methods.—Ten individuals each of four species of small anurans (*Pseudacris feriarum, Hyla chrysoscelis, Hyla cinerea,* and *Hyla squirella)* were collected in Macon Co., Alabama, USA, during the breeding season from a man-made pond (32.51529°N, 85.61183°W, WGS84). Snout–vent length (SVL) ranged from 2-4 cm. Upon capture each frog was placed in a clean clear plastic bag. We have found the snack-sized bags to be perfect for this application. The frog was oriented into the corner of the bag so the corner fit snuggly over the snout of the frog (Fig. 1). While holding the bag in the non-dominant hand, the frog was placed ventral side up on the lens of bright flashlight. Light emitting diode (LED) lights are preferable since the diodes will not generate heat like incandescent bulbs. By using the thumb and index finger of the non-dominant hand to limit the area of light like a diaphragm, internal organs, including the heart, are visible through the thorax. With the dominant hand an attempt at a blood sample was made by inserting the hypodermic needle directly through the bag into the ventricle (Fig. 2).

All sampling was performed with 26.5-gauge heparinized needles and 1-ml syringes. We deemed a sample a success if it was collected within 2 min and we were able to collect 50 µl of blood. All frogs were then placed into individual (~500 ml) plastic containers containing a moist paper towel and held for 48 h. After 48 h all individuals were released.

Results.—We were successful in collecting blood in 70% of *P. feriarum*, 80% of *H. squirella*, and 100% of *H. chrysoscelis* and *H. cinerea*. 100% of the frogs sampled by this technique survived to 48 h and no frog exhibited any outward sign of injury or distress.

FIG. 1. Proper orientation of *Hyla squirella* in the corner of a small plastic bag for cardiocentesis.

FIG. 2. Transillumination of *Hyla squirella* using a light emitting diode head lamp. The frog is restrained using a small plastic bag. The heart is medial (indicated by the needle), located superior to the liver, which is visible as a large dark mass.

Discussion.—Not injuring study animals is important for humane handling and critical in cases where repeated samples are required. Using our technique of bag restraint with transillumination increased the number of successful samples and decreased the potential mortality from cardiocentesis of small individuals. In previous studies we had roughly a 50% success rate in the smallest (2–3 cm) individuals and as high as 5% mortality rate (C. Ward, unpubl.). We feel that handling time was reduced using this method as well. Though we did not measure total handling time, we did see an increase in the number of successful samples within the prescribed 2-min handling period.

Bag restraint also limits skin to skin contact between researcher and frog. This has a few important implications. First, contact with frog skin can be detrimental to the frog and the use of gloves can exacerbate the effects of handling and in some cases cause mortality (Alford et al. 2008; Cashins 2008; Greer 2009; Schock et al. 2009). Secondly, the bags are an easy, disposable means of securing the anurans that could limit the spread/transfer of chytridiomycosis or ranavirus, both leading causes of population declines (Berger 1998; Speare et al. 1998; Chinchar 2002), if a clean bag is used for every sample. Lastly, skin secretions collected in plastic bags during handling can be used for later analysis if desired.

In conclusion, we feel that this technique is a useful tool for hematological studies involving small amphibians and will decrease stress, injury, and mortality while increasing sampling success and potentially decreasing the spread of disease.

Acknowledgments.—We thank Frank and Laucita Swinson for access to their pond. This research complied with all applicable institutional Animal Care guidelines, and animals were collected under Alabama State Scientific Collecting Permit issued to RDB.

A Critical Evaluation of Two Historic Records of Large *Python*

Humans have long been fascinated by large snakes, which invoke emotions ranging from fear and revulsion to curiosity, wonderment, and at times, veneration and reverence (Minton and Minton 1973; Morris and Morris 1965; Murphy and Henderson 1997; Pope 1961; Strothers 2004). From a scientific standpoint, reports of large reptiles are of interest from both an ecological and evolutionary perspective, and knowledge of asymptotic body size is a necessary prerequisite for understanding patterns of growth (Woodward et al. 1995). Much of what is known concerning the maximum body size attained by various giant snakes (species known to exceed 20 feet [609 cm] in total length *sensu* Murphy and Henderson 1997) is based on anecdotal accounts penned by explorers, travelers, colonial officials, and early naturalists, all with varying degrees of education and biological expertise (Minton and Minton 1973; Murphy and Henderson 1997). As such, these accounts are often difficult to interpret, but nonetheless can provide important insights into the biology of giant snakes (Murphy and Henderson 1997).

We here present two such historic records of large *Python* that have not previously appeared in the herpetological literature, and critically evaluate each based on criteria modified from Forman and Russell (1983) and Bates and Byrne (2007), namely: 1) Was the snake actually measured or is the reported body size simply an estimate?; 2) Is the account based on information recorded at the time of the observation (e.g., journal entry) or was it written from memory at some later date?; 3) Does other natural history information provided in the account suggest the author was a credible observer or one prone to exaggeration and embellishment?

The first record is provided in a travelogue authored by Charles Challié Long (1876) describing his explorations around Lake Victoria in modern-day Uganda. Challié Long, an American serving under General Charles "Chinese" Gordon in the Egyptian army, is credited with becoming the third westerner to visit Lake Victoria, discovering Lake Kioga, and pacifying indigenous tribes in the region (McLynn 1992). As stated in the account, on 13 September 1874 Challié Long was seated at his "accustomed place beneath a tree", when a local chieftain and 10 of his men appeared "dragging something that seemed … [to be] … the body of a tree". On closer inspection "it proved to be a huge boa constrictor they had just killed … and brought to me as a surprise. Supposedly a female, it measured thirty feet [914 cm] in length, and in diameter was the size of a child" (Fig. 1). Challié Long goes on to state that villagers claimed the snake "came nightly to suck … [milk from] … the cows" penned nearby. The discovery of a clutch of "boa" eggs within the walls of a grass hut and "countless small serpents" found the previous night led Challié Long to conclude the female snake had entered the village in search of her offspring.

Elsewhere in his travelogue Challié Long notes that the region surrounding Lake Victoria was "full of these reptiles," which were reportedly so feared that in some areas people slept with their legs either crossed or spread open into a "V" to discourage large snakes from swallowing them. Failure to sleep in this manner meant being "swallowed and digested ere morning" according to Challié Long. While Challié Long seems to consider this tale as nothing more than local folklore, he goes on to describe a personal encounter with another large snake. After having fallen asleep on a stream bank one night, "I was suddenly awakened by the consciousness of the pressure of something horrible. At my feet, its ponderous jaws wet with fatal horrible saliva, lay a huge boa." Only "the natural repulsion that had shocked my nerves … saved me from a Laocoon-like embrace" [reference to a fanciful description by the Roman poet Virgil of sea serpents that attacked Laocoön and his sons; see Strothers 2004] of the giant snake. Despite being "transfixed to the spot" and unable to move, Challié Long was able to alert some accompanying African soldiers who killed the snake, made a "savoury meal" of the carcass, and sliced the skin into strips to be worn "as charms against the devil."

The large constrictors that Challié Long (1876) encountered in Uganda were undoubtedly African Pythons (*Python sebae*) rather than the Common Boa Constrictor (*Boa constrictor*), which is restricted to Central and South America (Lee 1996); labeling any large constrictor a "boa constrictor" seems to have been a common literary convention of Victorian-era travel writers (e.g., Duncan 1847; De La Gironiere 1854). If the body length of 30 feet given by Challié Long is indeed accurate, the specimen he examined ranks among the five largest *P. sebae* ever recorded (Murphy and Henderson 1997). Notably, only one of

Fig. 1. Illustration from Challié Long (1876) showing a "huge boa constrictor" (actually *Python sebae*) killed near Lake Victoria in modern-day Uganda. The snake reportedly measured 30 feet long [914 cm].

these record-sized pythons was actually measured, a 31-foot [945 cm] specimen killed in West Africa (Duncan 1847).

There is little reason to doubt that Challié Long encountered large *P. sebae* during his African explorations; however, for several reasons we regard the reported body length of 30 feet as dubious at best. First, while Challié Long implies the snake was measured, this is not explicitly stated in the account. Second, the diameter reported for the snake ("the size of a child") is inconsistent with its purported length. According to Broadley (1984), a *P. sebae* measuring 600 cm in length has the girth of "a normal man's waist." Presumably a specimen 914 cm long would have a correspondingly greater diameter, certainly larger than that of a child. Third, there is little else in the travelogue to indicate that Challié Long was a credible naturalist. Other than brief comments on the abundance of dangerous wildlife, his account is notable for its paucity of natural history information, instead being largely devoted to descriptions of physical hardships and interactions with hostile tribesmen. His encounters with giant snakes seem to be just another of the many perils faced by the intrepid author rather than credible natural history anecdotes. Finally, although his travelogue appears to be based on a journal written in the field, modern historians have criticized Challié Long for a lack of accuracy (Clark 1967), casting doubt on the specifics of his narrative. Given these caveats, we are unable to accept the size record for *P. sebae* given by Challié Long (1876). In our view, the principal value of his narrative lies in its portrayal of Victorian attitudes towards large snakes and indigenous peoples and it should not be considered a reliable source of biological information.

The second account of a record-sized *Python* is found in the memoirs of Boris Hembry (2011), a British rubber planter who worked in Sumatra and Malaya (Malaysia) in the 1930s and later became embroiled in the Malayan Emergency after World War II. From January through December of 1931 Hembry managed a rubber plantation in Aceh Province of northern Sumatra, about 240 km north of the city of Medan. According to his account, while having breakfast one morning, Hembry was notified that laborers cutting brush beneath the rubber trees had just found a large snake. Grabbing a rifle, Hembry ran to the spot and found a "giant python fast asleep, having just had a meal—we were to find out later that it was a young pig." Although still alive, the snake had been beaten senseless by the laborers. So massive was the snake that 10 people were required to lift it. The snake was carried but a short distance before it revived and was again rendered unconscious by a rain of blows to its head. Hembry contacted a German professional hunter living nearby who administered a drug (thought to be opium) to "keep the snake unconscious until it could be killed and skinned," which was accomplished in due course. Hembry remarks that the python "was quite a remarkable specimen … its head was a good 12 inches [30.4 cm] across and when we eventually straightened it out it measured 33 feet 6 inches [1021 cm]." According to the German hunter, "it was undoubtedly the largest snake ever caught in the Far East, if not the world." Hembry photographed the snake before and after skinning it, but unfortunately these photographs were left behind in his haste to escape Malaya following the Japanese invasion in December 1941. Copies of the photographs were also distributed to friends and family living abroad, although none could be located by the time Hembry began writing his memoir. The skin of this snake was dried and later presented as a gift to the wife of his plantation manager who is thought to have taken it to Zurich, Switzerland when her husband retired. The current whereabouts of the skin are unknown, although Hembry speculates it "could be in a natural history museum." Interestingly, and in our opinion to his credit, Hembry concludes his account by stating "In retrospect, I am deeply sorry that this magnificent specimen of nature was slaughtered for a keepsake, like so many elephant, tiger and countless other magnificent creatures," a sentiment rarely expressed by those who slay large snakes or other megafauna.

The record-sized python described by Hembry (2011) was no doubt a Reticulated Python (*Malayopython reticulatus*, formerly *Python reticulatus*), a species known to reach lengths exceeding 900 cm and the only giant snake occurring on Sumatra (Murphy and Henderson 1997). If the body length given by Hembry is accepted, his specimen exceeds the previous record of 33 feet [1006 cm] reported for *M. reticulatus* (Raven 1946). It should be noted that the latter record is based on secondhand information obtained by Raven (1946) from a mining engineer who reportedly measured a large python killed on the Indonesian island of Sulawesi.

We see no reason to dismiss Hembry's account of what was apparently a record-sized *M. reticulatus* killed in northern Sumatra. As stated in the preface, the memoir was initially written "solely for his [Boris Hembry] family and not for publication." It was only after Boris Hembry died in 1990 that the memoir was published by the Hembry family, who believed the material was historically noteworthy and warranted a wider readership (John Hembry in Preface of Hembry 2011). Boris Hembry thus appears to have had no obvious motive for self-aggrandizement or embellishment to promote commercial sales or readership of his book; indeed Hembry directly addressed this issue in the Foreword when he stated, "I have made no attempt to romanticize or exaggerate … [when writing this account]." Furthermore, Hembry had considerable experience working outdoors and hunting, and other natural history anecdotes in the book appear to be those of a credible observer. Likewise, his accounts of fighting Communist guerillas in the Malayan Emergency do not appear those of a braggart. Our sole cause for concern is the fact that Hembry wrote his memoir many years after the events described actually occurred (the manuscript was written over a lengthy but unspecified period and completed in 1983). Although Hembry stated in the Foreword that "I have relied on memories, promptings from Jean [wife] and friends,

and *documents that I have retained* [italics added]," we cannot determine if the account of killing the python is based on notes written at the time of the event or memories recalled many years afterwards. The latter would temper our acceptance of the reported body length for as Bates and Byrne (2007) note, the human mind has an active constructional nature making it near-certain that recollections will change if they are recalled repeatedly before being recorded in hard form.

To briefly summarize, we do not dispute that Challié Long (1876) encountered large pythons while exploring what is now part of Uganda, but for reasons outlined above we place little credence in the purported length of the near-record sized *P. sebae* he described. In short, we consider his account nothing more than a highly embellished traveler's tale that nevertheless makes for enjoyable reading almost 140 years later. As a potential source of biological information however, its value is nil. In contrast, the snake described by Hembry (2011) appears to be an authentic size-record, although the possibility the account was written from memory is cause for concern. As is the case with so many accounts of large constrictors (Pope 1961; Murphy and Henderson 1997), there is no way to independently corroborate Hembry's size record. Even should the missing skin be located in a museum collection it would not be considered indisputable proof of the size of the living snake, because skins are easily stretched during preparation and drying (Murphy and Henderson 1997), sometimes by as much as 25% (Oliver 1958). Size estimates of large reptiles (snakes and crocodilians) based on dried skins are therefore ambiguous at best (Oliver 1958; Platt et al. 2009).

Because of logistic difficulties involved in preserving and transporting specimens of large reptiles (Murphy and Henderson 1997) and their notable paucity in museum collections (Barker and Barker 2008), written accounts, many of which are in historic sources rarely perused by biologists and yet to be uncovered, will no doubt remain important in the discussions regarding maximum body sizes attained by giant snakes. Although numerous pitfalls surround the interpretation of these accounts, we concur with Murphy and Henderson (1997) and maintain that careful evaluation based on rigorous criteria can provide valuable insights into the biology of giant snakes.

Acknowledgments.—We thank Madeline Thompson and the interlibrary loan staff at Wildlife Conservation Society (New York) for obtaining several obscure literature references, and Lewis Medlock for sharing his knowledge of giant snakes and critically reviewing an initial draft of this manuscript. The findings and conclusions in this article are those of the authors and do not necessarily represent the views of the U.S. Fish and Wildlife Service.

Absence of *Batrachochytrium dendrobatidis* in Eighteen Species of Amphibians from a Variety of Habitats in Tamaulipas, Mexico

Global amphibian declines have been a major concern for the past fifty years, and *Batrachochytrioum dendrobatidis* (*Bd*) is considered to be among the leading causes affecting amphibian populations (Berger et al. 1999; Houlahan et al. 2000; Lips et al. 2003; Stuart et al. 2004; Beard and O' Neill 2005; Brem et al. 2008; Brown et al. 2013; Philips et al. 2013). *Bd* has been detected in different wild amphibian populations in America (Knapp and Matthews 2000; Lips et al. 2004; Frias-Alvarez et al. 2008; Voyles et al. 2012). But currently there are no reports on *Bd* in amphibian populations from northeast Mexico. We were therefore interested to investigate amphibian populations for the presence of *B. dendrobatidis*, with specific focus on the state of Tamaulipas.

Tamaulipas is located in northeast Mexico, bordered by Texas, USA to the north, and the Gulf of Mexico to the east. Portions of four major biogeographic provinces occupy Tamaulipas: Tamaulipan, Sierra Madre Oriental, Chihuahuan Desert in the Nearctic and the Veracruzan in the Neotropical region (Alvarez 1963; Flores-Villela 1993; Morrone et al. 2002). The Tamaulipan province (Fig. 1, Table 1) is a semiarid region, characterized by deciduous and thorny plants interspersed with grassland (Blair 1950; Johnston 1963). The majority of the province is confined to the Gulf coastal plain, with mountains rising to an elevation of 2250 m above sea level in the southwest corner of the state of Tamaulipas. The temperature of the province is relatively high throughout the year, with average highs around 32°C, and lowest temperatures at 15°C. In the lower elevations the vegetation consists mostly of semiarid tropical thorn scrub, with thorn forests of acacia, mesquites, and cacti (Martin 1958; Alvarez 1963; Flores-Villela 1993; Morrone et al. 2002; Cram et al. 2006). The lower mountains have an elevation range between 600–1400 m, surrounded by tropical deciduous forest and montane scrub or pine-oak forest (Martin et al. 1954). Elevations that are over 2250 m such as summits and higher interior slopes support dry oak and dry pine-oak forest, and temperate Madrean pine-oak woodlands (Martin 1958; Gómez-Hinostrosa and Hernández 2000).

We tested a total of 56 wild-caught amphibians from the state of Tamaulipas for the presence of *Bd* (Table 1), sampled from 2005 to 2007. All samples belong to the MRJ Forstner Tissue collection at Texas State University and were collected from adult frogs that appeared to be in healthy condition using swabbing or non-consumptive toe clipping. Temperature data were obtained from the three weather stations that belong to the INIFAP (Instituto Nacional de Investigaciones Forestales Agrícolas y Pecuarias) in Mexico.

DNA was extracted from the swabs using PrepMan assay and from toe clips using a DNeasy Qiagen Kit, tissue protocol (Gaertner et al. 2009; Kilburn et al. 2010). The presence of *Bd* was assessed using a real time Taqman *q*PCR assay (Boyle et al. 2004; Kilburn et al. 2010). The assays were conducted in triplicate for each sample. Only quantifications having an efficiency between 90 and 110% (average of 98.15%) and an R^2 values higher than 0.997 were considered.

None of the samples tested positive for *Bd*. Considering the previous studies done in Mexico that show positive samples (Lips et al. 2004; Frias-Alvarez et al. 2008) we were expecting to find the pathogen present, especially given that species considered carriers of the pathogen were sampled (Garner et al. 2006).

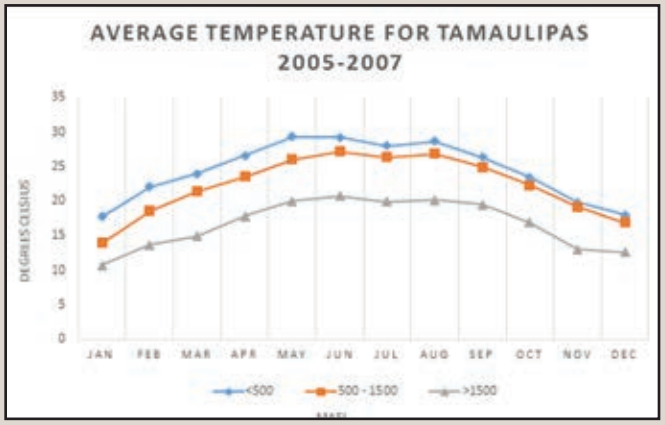

FIG. 2. Average monthly temperatures at three different elevations during 2005–2007 from Tamaulipas, Mexico.

Our results suggest that these amphibian communities have not been in contact with the fungus, or that they have developed different mechanisms that make them immune or resistant to *Bd* infections (Lips et al. 2004; Voyles et al. 2012; Philips et al. 2013). Our evaluation was part of a sampling process for a preliminary biodiversity assessment, consequently our findings should not be seen as definitive for the prevalence of *Bd* in the state of Tamaulipas. It is important to continue surveys in the area as well as the adjacent states, not only looking for presence and prevalence of *Bd*, but also to determine the actual abundance of amphibians in the different regions to assess population status.

To evaluate if temperature was a factor that could have negatively impacted the presence of the pathogen during the time when samples were collected, we analyzed temperature data from 2005 to 2007. During this period the temperature was higher on average during the months of collection for the elevations from 0–1500 m than what has been reported as being optimal for growth of *Bd* (Piotrowski et al. 2004), while for elevations above 1500 m it was between 5°C and 20°C and thus within adequate temperature conditions for *Bd* growth (Fig. 2). Therefore temperature does not seem to be the critical factor acting to explain the absence of *B. dendrobatidis* detections from amphibian species in the region.

Several studies have reported on the spread of *Bd* southward out of Central America and into South America (Pounds et al. 1997; Campbell 1998; Lips 1998; McCranie and Wilson 2002; Lips et al. 2003; Kilburn et al. 2010; Becker et al. 2012; Philips et al. 2013). However, there have not been complementary investigations that seek to track the pathogen northward out of Mexico, and if that is still possible. This investigation of samples from northern Mexico shows no positive samples for *Bd* and no relation between the presence of the pathogen and the optimal temperatures for pathogen growth previously reported in the *Bd* literature (Fig. 2).

In the analyses by Olson et al. (2013), altitude was not considered as a critical factor in the distribution of *Bd* provided factors such as temperature, precipitation, and species richness were favorable. To our knowledge, Olson et al. (2013) is the only paper that includes altitude into the model and found it to be non-significant. In our study it is not possible to determine if altitude has a significant effect on infection variation, but it is possible to infer if temperature variation has an effect in the absence of the pathogen.

Our detection of *Bd* might be affected by the overall small sample size leading to a false negative prevalence. However, studies done in southern Mexico show 84% prevalence of the pathogen (Frias-Alvarez et al. 2008). If we extrapolate those results to our samples in Tamaulipas, then from 56 samples collected at least 48 of them (84%) would be positive. There is another study done in northwest Mexico where the prevalence of *Bd* was 60% (Saenz et al. 2010). If this prevalence rate were to be extrapolated to our results then at least 34 samples would be positive for *Bd*. Further sampling including a larger total number of animals needs to be completed to better assess if the State of Tamaulipas is free of *Bd*. Additional studies with continuous sampling throughout the year could account for seasonal variation, not accounted for in our study, and a different design could take into account factors that might act to prevent widespread prevalence of the disease such as elevation, amphibian abundance studies, and amphibian species richness.

Acknowledgments.—Fieldwork was conducted under SEMARNAT permits: 1624/05; 0800/06; 1085/07; 1255/08, with partial funding provided by Houston Zoo, Inc. Within the United States, *Batrachochytrium dendrobatidis* (*Bd*) is widespread (Olson et al. 2013) and has been recently introduced into several natural areas (Weldon et al. 2004; Kolby 2014) and it continues to be implicated in the extinction, extirpation, and/or declines of amphibian populations around the world (Daszak et al. 2003; Lips et al. 2006; Longcore et al. 2007; Dodd 2010; Kilpatrick et al. 2010; Eskew and Todd 2013; Olson et al. 2013). The American Bullfrog (*Lithobates catesbeianus*) is the only ranid species from North America that has been cited as a contributing factor in the global spread of *Bd* (Schloegel et al. 2012; Gervasi et al. 2013a). This is largely due to it being farmed or traded internationally (e.g., research, medicinal, food source, pet trade), but this is further exacerbated by it being a potentially invasive species that is resistant toward developing symptoms of the disease chytridiomycosis (Daszak et al. 2004). The latter is presumably due to its host-pathogen interactions (Rollins-Smith et al. 2011), highly keratinized skin, and vagility. Because of these factors, it has been suspected to be a *Bd* carrier (Lannoo et al. 2011) or reservoir (Fisher et al. 2009). Our study objective was to determine the prevalence of *Bd* in two species of frogs from the family Ranidae (*Lithobates catesbeianus* and the Green Frog,

GRAPHIC PREPARED BY NYSSA HUNT

FIG. 1. An aerial photograph (NAIP Imagery, <1 m spatial resolution, released Aug 21, 2014) depicts the developing landscape surrounding the study site (LT6, Hamilton County, Tennessee, USA) where the prevalence of *Batrachochytrium dendrobatidis* was investigated in two ranid frog species. The wetland boundary is highlighted by the white polygon in the center of the frame.

L. clamitans) at a site in southeastern Tennessee, USA, a region where *Bd* surveys have not yet been conducted. Both species are ideal candidates for co-monitoring because they are sympatric congeners, have similar ecologies (Conant and Collins 1998), and *Bd* has been known to occur in both species (Ouellet et al. 2005). Hence, we tested the hypothesis that *L. catesbeianus* would have relatively equal rates of *Bd* prevalence when compared to an ecological equivalent, *L. clamitans*.

The study site, herein referred to as LT6 (35.104°N, 85.130°W; average elevation of 180 m), is an ephemeral wetland surrounded by mixed hardwood forest and is located on a former United States Department of Defense (DoD) installation (Volunteer Army Ammunition Plant) and lies adjacent to an industrial park, a mixed-use natural area, and an outdoor university classroom (Fig. 1; Armstrong 2012; Simpson 2013). LT6 is owned and managed by the University of Tennessee at Chattanooga. It is nestled in the Ridge and Valley ecoregion (Griffith et al. 1997), and the underlying geology is dominated by limestone and karst formations and the topography ranges from rolling hills to steeper slopes (Griffith et al. 1997). The upland habitat is characterized by approximately 32.8 ha of eastern deciduous forest that is dominated by mixed hardwoods (e.g., *Liriodendron tulipifera* [Tulip Poplar], *Platanus occidentalis* [Sycamore], *Fagus grandifolia* [American Beech], *Ulmus alata* [Winged Elm], *Quercus* spp. [oaks], *Carya* sp. [hickory], *Fraxinus* sp. [ash]), with some interspersed pines (*Pinus* sp.), and an invasive colony of Chinese Privet (*Ligustrum sinense*). The wetland is dominated by a wooded over-story, consisting of three interconnected pools that total 4.1 ha. Hydroperiod varies by year, season, precipitation, and temperature; and during the typical wet season, water depth ranges from 25 to 54 cm. The upland and aquatic habitats at LT6 create a synergy that yields minimally 43 species of amphibians and reptiles (Simpson and Wilson 2009; Simpson et al. 2010; Armstrong 2012; Wilson et al. 2012; Simpson 2013; Wilson, unpubl. data). Prior to 2008, LT6 received some protection from development as a former DoD installation, and was largely buffered on the eastern, western, and southern borders by an additional 230 ha of intact upland forest.

For biosecurity, we wore powder-free nitrile gloves when capturing animals or processing samples. To further minimize *Bd* cross-contamination, all animals were temporarily placed into individual plastic bags in an effort to ease restraint when swabbing, and decrease handling time. All equipment that physically contacted an animal was disinfected using 70% EtOH (Hanlon et al. 2012) before and after use. All gloves, plastic bags, swabs or similar items were changed between subsequent captures or samples and were properly disposed of following approved biohazard protocols. All other equipment was treated with an aqueous solution of chlorine bleach (i.e., 10% by volume; Johnson et al. 2003) and the process was repeated three times for a total soak time of 30 minutes. This latter decontamination procedure was conducted before entering and exiting the study area.

We captured *L. catesbeianus* and *L. clamitans* randomly by hand using visual encounter surveys from 4 October 2012 to 26 December 2012 around the periphery of the wetland at LT6. All frogs were measured for total body length (TBL) via straight-line to the nearest 1.0 mm using dial calipers. We swabbed the ventral and medial surface of the thighs and abdomen, as well as the webbing on the hind feet for a total of 45 sec using aseptic technique (Vredenburg and Briggs 2009). All frogs were individually marked using the scheme of Martof (1953) and photographed after swabbing. The polyester (Dacron) swabs (Fisherbrand, Cat. #14-959-90; Pittsburgh, Pennsylvania, USA) and any transferred *Bd* DNA were placed in 1.5-ml microcentrifuge tubes with screw caps (Fisher Scientific, Cat. # 02-682-557; Pittsburgh, Pennsylvania, USA) containing cold 70% EtOH and stored at -80°C prior to analysis.

Each sample was dried in a speedvac (Labconco, Centrivap DNA Concentrator; Kansas City, Missouri, USA) prior to DNA extraction. The residual was re-suspended in 200 µL of lysis buffer along with 0.3 g of sterile, inert glass beads and 200 µL of Phenol:chloroform:isoamyl-alcohol (25:24:1). This addendum was adapted from a modified yeast DNA extraction protocol (Hoffman 1997) and was used along with a Mini-BeadBeater (BioSpec Products; Bartlesville, Oklahoma, USA) for 45 sec followed by 60 sec on ice and this process was repeated three times to successfully homogenize and extract DNA from all samples. We added 200 µL of Tris-EDTA buffer to the homogenate, vortexed it for 5 sec, and centrifuged it for 5 min at 15,000 rpm. The aqueous solution in the upper portion of the microcentrifuge tube containing the extracted DNA was transferred to a new microcentrifuge tube for purification. The final concentrate of DNA was quantified using a spectrophotometer (Thermo Scientific, Nanodrop 2000C; Waltham, Massachusetts, USA). We used a modified PCR (Eppendorf Master Cycler Gradient) analysis following the initial methods of Boyle et al. (2004) using a controlled reaction containing cloned spore DNA fragments. The *Bd* gDNA clone was obtained from the Center for Wildlife Health at the University of Tennessee-Knoxville (Matt Gray and Debra Miller, pers. comm.). Each plate contained these standards and served as positive and negative controls in our analysis. All samples were run in triplicate and all positives were assayed by PCR independently a total of four times to ensure accurate results.

We used Chi-Square Tests (Exact Binomial Goodness of Fit Test [two-tailed], Yates' correction for continuity [two-tailed]; Sokal and Rolf 1995) to evaluate the presence and absence of *Bd* in two closely related species of ranid frogs from LT6. We calculated probabilities of detection (POD) using DiGiacomo and Koepsell's (1986) equation:

$$C = 1 - (1 - p)^n$$

TABLE 1. Results of *Batrachochytrium dendrobatidis* (*Bd*) sampling in two ranid species from an isolated wetland at a former Department of Defense installation in southeastern Tennessee, USA. POD is the probability of detecting at least one *Bd*-positive individual for a particular species with a disease prevalence of at least 5, 10 or 30%.

Species	Date Sampled	No. *Bd*-positive Total No. Sampled (Prevalence)	POD	
Lithobates catesbeianus	13 Nov. to 26 Dec. 2012	3/51 (0.0588)	p = 0.05	0.929
			p = 0.10	0.992
			p = 0.30	0.999
Lithobates clamitans	04 Oct. to 25 Dec. 2012	10/26 (0.3846)	p = 0.05	0.737
			p = 0.10	0.935
			p = 0.30	0.999

where *C* is the probability of detecting at least one *Bd* positive individual from a representative sample (*n*) and the plausible prevalence of the disease (*p*) expressed as a fraction ranging from 0 to 1 (e.g., 0.05, 0.10, 0.30; Canessa et al. 2013).

We swabbed 77 frogs and detected *Bd* in 5.88% (3 of 51) and 38.46% (10 of 26) of *L. catesbeianus* and *L. calmitans*, respectively (Table 1). *Bd* occurrence differed between the two species (Exact Binomial Goodness of Fit Test p = 0.000254, Yates' correction for continuity $\chi^2 = 14.003$, p = 0.000183, df = 1; Sokal and Rolf 1995). However, based on POD calculations, we are 92.9% and 73.7% confident that *Bd* would be detected in *L. catesbeianus* and *L. clamitans* at a prevalence rate of at least 5%, respectively (Table 1). No ranid frogs showed clinical signs of *Bd* infection (e.g., skin lesions, edema, non-responsiveness).

Our *Bd* survey is the seventh to be conducted in Tennessee (see Rothermel et al. 2008; Venesky et al. 2008; Chatfield et al. 2009; Davis et al. 2012; Hanlon et al. 2012; Rollins et al. 2013), but is the first from southeastern Tennessee (http://www.bd-maps.net) and the only one in the published literature that was conducted on a former DoD property in Tennessee. Although, we detected *Bd* in both species of ranid frogs, *L. clamitans* had higher relative rates of prevalence when compared to *L. catesbeianus*. This result was contrary to our hypothesis that *L. catesbeianus* and *L. clamitans* would have relatively equal rates of *Bd* prevalence due to their ecological similarity. However, other research has suggested that *L. catesbeianus* has higher levels of *Bd* prevalence on average when compared to *L. clamitans* (~27% and ~20% for *L. catesbeianus* and *L. clamitans*, respectively; Ouellet et al. 2005). There are several possible explanations for the difference in *Bd* prevalence for the two ranid species, including temporal patterns of infection, host immunity, competition, or sensitivity to landscape change. *Bd* may be most prevalent during the late spring or summer months (Lannoo et al. 2011) and because our samples were collected during the fall it is possible that with *L. catesbeianus* being somewhat resistant to *Bd*, they could have lower rates of infection when compared to *L. clamitans*. Hence, prevalence at other times of the year may differ from our findings.

Previous research has indicated that there is considerable variation in host susceptibility to *Bd* (Searle et al. 2011; Hanlon et al. 2012) and no clear pattern exists among species except for the idea that some ranid frogs may be more resistant to *Bd* or that their clinical response is more variable when compared to other anurans (Gervasi et al. 2013b). For example, the Mountain Yellow-legged Frog (*Rana muscosa*) is nearing extinction even though it produces a higher amount of total skin peptides that have antimicrobial properties when compared to those of the Northern Leopard Frog (*L. pipiens*; Rollins-Smith et al. 2006). Perhaps, in our scenario, *L. clamitans* at LT6 are stressed due to extrinsic factors from exurban development involving the recent and large-scale loss of habitat from the expansion of the adjacent industrial park (Armstrong 2012; Simpson 2013) or competition from *L. catesbeianus* (or other amphibians) and have become immunocompromised making them more sensitive to *Bd*. If this were the case, *L. clamitans* could have a proportionately higher rate of *Bd* prevalence as seen at LT6. Similarly, others have suggested that the epidemiology of *Bd* within a community is likely driven by a suite of factors and cannot be attributed to one variable alone (Navas et al. 2012). While the aforementioned remains largely untested here, it parallels the ecological findings of others at LT6. Simpson (2013), over a 33-month period observed an increase in the relative abundance of *L. catesbeianus* when compared to other ranid species. The factors that were contributing to the shift in species composition were largely undetermined, but a synergy of intrinsic and extrinsic factors is plausible.

Bd continues to be a concern for conservationists and those who study amphibian communities; therefore, an integrated approach is necessary to adequately address amphibian declines and to develop adaptive conservation and management strategies. Collectively, 16.88% of all frogs tested in our study were positive for *Bd*, and all were found in microhabitats suitable for a variety of amphibian, reptile, and invertebrate taxa. This study, while limited seasonally, geographically, and taxonomically, provides baseline data that furthers our understanding of the distribution and prevalence of *Bd* in the southeastern United States—a biodiversity hotspot. Surveys for *Bd* that incorporate a wider range of taxa and habitats can better elucidate the role of competition, ecological persistence, asymptomatic carriers, and exurban development. Therefore, further investigation is warranted to better determine if *Bd* is endemic and widespread across the amphibian community described here.

Acknowledgments.—Support for this project was provided by The University of Tennessee at Chattanooga (Biology SUF-TPW #E041011), The Lupton Renaissance Gift Fund (#R040152003), NBII/USGS (#R041011026), and volunteers. The field portion of this research was conducted under Tennessee Wildlife Resources Agency Permit 3082. All research was conducted in accordance with approved

protocols (IACUC: #0907TPW-03 and #0408TPW-04; IRB #12-136). Special thanks are given to Matt Gray and Debra Miller for providing us with ~500 ng chytrid gDNA. We express our gratitude to Penni Jo Wilson for providing comments on earlier versions of the manuscript and logistic support. Andrew Methven provided additional information on literature and points of contact. Nyssa Hunt assisted with mapping and graphics. Special thanks are extended to Daniel Armstrong, Joe Simpson, Chris Manis, Stefan Moss, Kat Harris, and Daniel Sims for assistance. We thank TPW's field crew (Team Salamander) for their efforts and these include, Ardyce Mercier, Nyssa Hunt, Robert Altonen, Brittany Bird, Patricia Garland, Wes Grigsby, Jeremy Hooper, Brittany Killian, Simone Madsen, Katherine Smith, Paul-Erik Bakland, Sarah Bohr, Mark Wisdom, Mark Dillard, Emily Busby, Liz Staundt, Jade Scott, Alicia Phillips, Charles Norton, Charles Strange, George Szarka, James Kee, Elijah Reyes, Hassan Hussein, John Burke, and others that we have likely forgotten but appreciate no less.

Chytrid Fungus (*Batrachochytrium dendrobatidis*) Undetected in the Two Orders of Seychelles Amphibians

Infection by the fungal pathogen *Batrachochytrium dendrobatidis* (*Bd*) is a major driver in global amphibian declines (Berger et al. 1998; Skerratt et al. 2007) and can occur in all three orders of Amphibia, having been most recently documented in the Gymnophiona (Doherty-Bone et al. 2013; Gower et al. 2013). *Bd* has been detected in 71 countries and 695 amphibian species (Olson and Ronnenberg 2014) but to our knowledge no screening for its presence or anecdotal evidence of chytridiomycosis has been reported from the Seychelles Archipelago, a biodiversity hotspot (Myers et al. 2000) with a very high proportion (86%) of endemic amphibian genera (Poynton 1999) (Fig. 1).

Eleven of the 12 species of Seychelles amphibians (Table 1) are globally significant. The four species of sooglossid frog are unique in being the only amphibian family endemic to an island group, and the endemic radiation of six Seychelles caecilians make them the only Gymnophiona to occur on continental islands. The single hyperoliid frog species occurring here is endemic to the Seychelles, leaving the single ptychadenid frog as the only non-endemic amphibian (Nussbaum 1984). Being primarily fossorial, caecilians are considered difficult study organisms and collection usually requires dedicated

digging (Gower and Wilkinson 2005), such that there have been few caecilian *Bd* field surveys (Gower et al. 2013). Similarly, sooglossid frogs are cryptic in their habits, undergoing direct development as part of a completely terrestrial life cycle in often inaccessible, elevated areas of moist forest (Nussbaum 1984; Nussbaum and Wu 2007). In contrast, the Seychelles Treefrog (*Tachycnemis seychellensis*: see Maddock et al. 2014), and the likely introduced Mascarene Ridged Frog (*Ptychadena mascareniensis*: see Vences et al. 2004) can be easier to encounter, forming breeding aggregations around marshes, streams, and temporary pools, especially in the evening (*T. seychellensis*) and/or after rain events (*P. mascareniensis*) (Nussbaum 1984). *Bd* is known to infect *P. mascareniensis* in mainland Africa (www.bd-maps.net/surveillance/s_species.asp; accessed 3 March 2014; Goldberg 2007), while Olson et al. (2013) identified a 50% prevalence of *Bd* in African Hyperoliidae, the family to which *T. seychellensis* belongs.

Between May 2010 and March 2013, skin swabs were taken from wild-caught caecilians and metamorphosed anurans at multiple locations across six of the Seychelles' inner islands (Fig. 2). All sampled specimens were swabbed alive and within 24 hours of capture, using rayon-tipped MW100 fine-tip swabs (Medical Wire and Equipment, Corsham, Wiltshire, England). Swabbing protocol generally followed best-practice methods available at the time (e.g., Smith 2011). However, our sampling was undertaken by three separate research groups operating over the period, with differing primary research aims. Therefore, some deviation from standard biosecurity protocol did occur, including capture and initial handling of amphibians without gloves, and (although infrequent) housing more than one animal (but always of the same species) in the same plastic bag upon capture. The principle aim was to gather a representative sample from sites within broadly separate locations, and not to swab every individual encountered or captured. A large proportion of sooglossid frog swabbing was undertaken in the field by a single person (JL). These mostly very small anurans (except for individuals of *Sooglossus thomasseti* measuring greater than 25 mm snout–vent length) were cleaned of debris and soil by transferring them to a small plastic zip-lock bag and rinsing with fresh water sourced at the sampling locality. Although this rinsing may have removed some zoospores, it was performed to reduce the increased likelihood of PCR inhibition. The water was then drained and the animal gently restrained and swabbed within the bag, removing the need for direct handling and minimizing risk

TABLE 1. Distribution of Seychelles amphibians (adapted from Nussbaum 1984), including the 2009 discovery of Sooglossidae on Praslin (Taylor et al. 2012) and their IUCN Red List status (IUCN 2013): LC – Least Concern; EN – Endangered; CR – Critically Endangered. Caecilian taxonomy follows Wilkinson et al. (2011).

of cross-contamination. Larger anurans, and sooglossid frogs processed when field assistance was available, were sampled using the standard technique (Smith 2011). Caecilians were swabbed dorsally, laterally, and ventrally along the length of the body, and also around the vent and head. Gloves were changed between each individual except where two or more specimens had been housed in the same plastic bag. All amphibians not retained as vouchers as part of broader research aims were released at their place of capture. Swabs were kept in the dark and transferred to cool storage, mostly refrigerated within 12 h and frozen within one week of completed fieldwork.

DNA extractions and quantitative real time Taqman® polymerase chain reaction (qPCR) assays were performed at the Institute of Zoology (London, UK), using methods adapted from Boyle et al. (2004). DNA was extracted from swabs using bead beating with 0.5 mm silica beads and 60 µl PrepMan Ultra (Hyatt et al. 2007). The qPCR amplifications were performed in 25 µl reactions using *Bd* primers ITS-1 (forward): 5'-CCT TGA TAT AAT ACA GTG TGC CAT ATG TC-3' and 5.8S (reverse): 5'-AGC CAA GAG ATC CGT TGT CAA A-3', specific to the ITS-1/5.8S region of rDNA (Boyle et al. 2004). Standards of 100, 10, 1 and 0.1 *Bd* DNA genomic equivalents and negative controls were used in each run. Bovine serum albumin (BSA) was included in the TaqMan® master mix, to reduce inhibition of the PCR (Garland et al. 2010). Each sample was run in duplicate and no amplification in either replicate indicated a negative result.

A total of 291 skin swabs were obtained from Seychelles amphibians, representing 10 of the 12 species known to occur across the archipelago. All 213 anurans and 78 caecilians tested negative for *Bd* (comprising 66 *Sooglossus sechellensis* [Fig. 3]; 13 *S. thomasseti*, 14 *Sechellophryne gardineri*, 99 *Tachycnemis seychellensis*, 21 *Ptychadena mascareniensis*, 18 *Grandisonia alternans* [Fig. 4], 7 *G. larvata*, 10 *G. sechellensis*, 6 *Hypogeophis brevis*, 23 *H. rostratus*, 14 unidentified caecilians) (Table 2). No macroscopic presentation of chytridiomycosis-like symptoms or associated mortality was observed in any sampled individual, or in any amphibian encountered during the fieldwork. Our results suggest a widespread absence of *Bd* between 2010 and 2013 across six of the eleven amphibian-inhabited islands of the Seychelles archipelago. Some caution should be exercised in interpreting our results as indicating that the Seychelles are free of *Bd*. Many of the locations sampled were in close proximity to one another and/or linked by contiguous habitat, and so could be described as a single location for the purposes of achieving the recommended minimum sample size of 30 amphibians per site (Smith 2011), but the temporal differences between site surveys and overall limited sampling invariably resulted in this not being achieved (Table 2), leading to the possibility of type II errors. Also, the recommendation for sampling >59 individuals to detect *Bd* when infection rate is low (Skerratt et al. 2008) was achieved for only two species sampled (*T. seychellensis*, *S. sechellensis*), two islands sampled (Mahé and Praslin), and for the two pooled samples of all anurans and all caecilians. Prevalence of *Bd* infection in anurans indicates seasonal peaks in the cooler months (Berger et al. 2004; Retallick et al. 2004; Kriger and Hero 2007) even with little seasonal temperature variation (Whitfield at al. 2012). Sampling of Seychelles amphibians was not undertaken during the two (historically) coolest months of July and August. However, housing more than one animal in the same capture bag, although limited in occurrence, increased the opportunity for cross-contamination from chytrid zoospores, making detection of *Bd* more likely by fostering false-positive results for infection.

TABLE 2. Numbers of amphibians sampled for *Batrachochytrium dendrobatidis* across six Seychelles islands. No samples were *Bd*-positive. Sampling localities shown in Fig. 2.

Direct development—a reproductive mode adopted by the Sooglossidae and at least one Seychelles caecilian (*H. rostratus*; Nussbaum 1984)—may provide a limiting factor to the transmission of *Bd* between and among amphibians (Todd 2007; but see Longo and Burrowes 2010). The probably more vagile *T. seychellensis* and *P. mascareniensis* require water bodies for aquatic larval development, and potentially present more suitable hosts for the dispersal and spread of *Bd*. Due to previous evidence of human-mediated trans-oceanic dispersal (Vences et al. 2004), *P. mascareniensis* in particular may lend itself to continuing introduction and transportation by way of tourist and/or domestic traffic, especially among the main islands of Mahé, Praslin, and La Digue (Fig. 1). This species' propensity for dispersal was evidenced first-hand during fieldwork following the discovery of a novel, reproducing population on North Island. Similarly, and despite no currently recorded infection or capacity as a host for *Bd* (www.bd-maps.net/surveillance/s_species.asp; accessed 21 September 2014), the recent discovery of Asian Common Toads (*Duttaphrynus melanostictus*) on the east coast of Madagascar, having likely arrived in shipping containers from Asia (Kolby 2014a), highlights a further risk to Seychelles endemic fauna as a potential disease vector. The significantly shorter shipping distances among Madagascar, the Mascarenes, and Seychelles islands undoubtedly elevates the risk of further human-mediated dispersal of this potentially invasive species.

Links between climate, temperature, and *Bd* have been documented (see Pounds et al. 2006; Bosch et al. 2007; Lips et al. 2008; Rohr and Raffel 2010; Olson et al. 2013). In tropical regions, elevated, moist, and riparian habitats are home to amphibian species considered most likely to be severely threatened by *Bd* (Wake and Vredenburg 2008). The endemic Seychelles amphibians fall into at least two, and often all three of these categories which, combined with their restricted range, highlights the requirement for targeted conservation measures (Sodhi et al. 2008). In light of the recent discovery of *Bd* in Malagasy anurans (Kolby 2014b), and given the potential susceptibility of Seychelles amphibians, continued disease monitoring warrants consideration as part of ongoing conservation work for this globally significant amphibian community. Effective implementation of Seychelles' recently approved Biosecurity Act (Animal and Plant Biosecurity Act, 2014) is consistent with maintaining such vigilance.

Acknowledgments.—This research was supported by the Durrell Institute of Conservation and Ecology; The Natural History Museum, London; University College London; Seychelles Islands Foundation; Institute of Zoology; Seychelles National Parks Authority; The Systematics Association; BBSRC's SynTax scheme; and the Darwin Initiative (grant 19-002). We thank T. Garner for facilitating laboratory work at the Institute of Zoology, London; Seychelles Bureau of Standards for permission to carry out fieldwork; Seychelles Department of Environment for permission to collect and export samples; Islands Development Company for permissions and hosting on Silhouette; Island Conservation Society for field assistance on Silhouette; M. La Buschagne for access to Coco de Mer Hotel land on Praslin; North Island Seychelles for permissions and hosting on North Island; R. Bristol, R. Griffiths, and J. Groombridge for organisational and field assistance; K. Beaver, D. Birch, P. Haupt, M. Jean-Baptiste, C. Kaiser-Bunbury, J. Mougal, M. Pierre, N. Pierre, D. Quatre, A. Reuleaux, H. Richards, A. Roberts, and many other NGO staff, researchers, and Seychellois for their in- and ex-situ support. We also thank D. Olson and an anonymous reviewer for helpful suggestions on a previous draft of this manuscript.

Yuman Fringe-toed Lizard (*Uma rufopunctata*) Care and Breeding at the Phoenix Zoo

Fringe-toed lizards (Phrynosomatidae: *Uma* spp.) are a unique genus, highly adapted to the native windblown, fine, sandy habitats of the southwestern U.S. and northwestern Mexico (Stebbins 1985). They possess a flattened body and tail, a countersunk jaw, and a chisel-like snout—all traits that allow them to rapidly burrow under loose sand. Overlapping and inter-locking eyelids, valves in the nostrils (Stebbins 1943), and flaps covering the ears keep the fine sand out of these orifices. Extended, elongated scales on the rear toes allow the species to run more easily on loose sand (Stebbins 1985; Brennan and Holycross 2006; Lemm 2006).

Uma has undergone some recent taxonomic changes (Heifetz 1941; Crother et al. 2003). Although first described by Cope in 1895, the Yuman Fringe-toed Lizard (*U. rufopunctata*) was considered a subspecies of the Colorado Fringe-toed Lizard (*U. notata*) until recently (Trepanier and Murphy 2001). *Uma rufopunctata* is a medium-sized lizard, up to ca. 120 mm snout–vent length (SVL). They are restricted to windblown, sandy dunes, flats, and washes in the most arid areas of extreme southwestern Arizona (Yuma Co.), USA and northwestern Sonora, Mexico (Brennan and Holycross 2006; Turner and Rorabaugh 2009). Both the habitat and lizard are sensitive and threatened by off-road vehicle use (Bury and Luckenbach 1983; Luckenbach and Bury 1983; Jennings and Hayes 1994), climate change, and agricultural and commercial development (Bagne and Finch 2012). Additionally, the geographic range of *U. rufopunctata* is small, encompassing less than 2000 km^2 (Hammerson et al. 2007). Consequently, the Center for Biological Diversity petitioned the U.S. Fish and Wildlife Service to move the classification of this species from Near Threatened (Hammerson et al. 2007) to Endangered in 2012 (Adkins Giese et al. 2012).

Numerous traits of *Uma* spp. have been examined (e.g., Heifetz 1941; Stebbins 1944; Earle 1962; Carpenter 1963; Turner 1998; Turner and Schwalbe 1998). Mayhew examined testes and ovaries of field-collected *U. inornata* (1965), *ornata* (1966a), and *scoparia* (1966b) to determine the breeding cycle of males and females. Similarly, Goldberg (2012) examined preserved specimens to describe the reproductive cycle in *U. rufopunctata*. Still, due to recent taxonomic changes (Heifetz 1941; Crother et al. 2003) and a lack of current research on the genus, much remains unknown about fringe-toed lizards.

The Phoenix Zoo received 3.4 *U. rufopunctata* from the Arizona Game and Fish Department on 12 June 2012. Currently, all animals housed by Association of Zoos and Aquariums (AZA) facilities are animals that originated from our 3.4 founders. We have created a managed breeding program for the species in an attempt to supply animals to interested AZA-accredited zoos across the country, while creating a sustainable *ex situ* population. We have also gained additional information about their needs, natural history, and growth, described here.

Captive husbandry.—During 2013, all animals were maintained either on exhibit (2.3 animals at a time) or in a breeding enclosure (one pair at a time). Both breeding and exhibit enclosures were glass tanks measuring ca. 91 x 46 x 43 cm with sand substrate and rocks for basking under an overhead Exo Terra® 160-watt Solar Glo UV/heat bulb. Temperatures ranged from 43°C on the sand surface under basking lights to 28°C. Although warmer basking was offered via perching, animals would not climb, preferring to bask in the top layer of sand, on the sand surface or on rock surfaces. Each breeding enclosure also contained two nest boxes, 6-qt. plastic, open-topped containers measuring ca. 38 x 23 x 15 cm. One container was

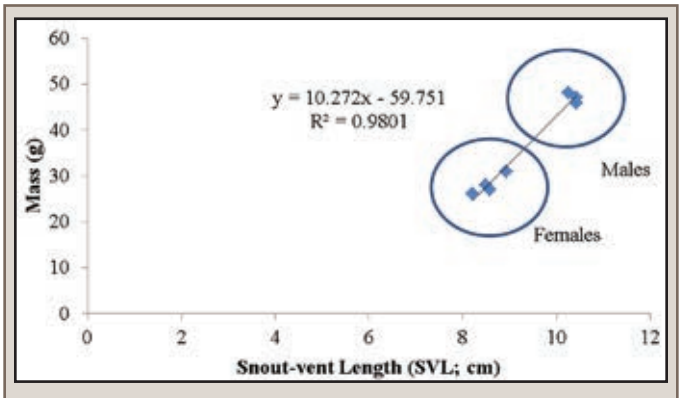

FIG. 1. Mass (g):snout–vent length (SVL; cm) ratio as measured on 10 May 2014 of all adult *Uma rufopunctata* at the Phoenix Zoo.

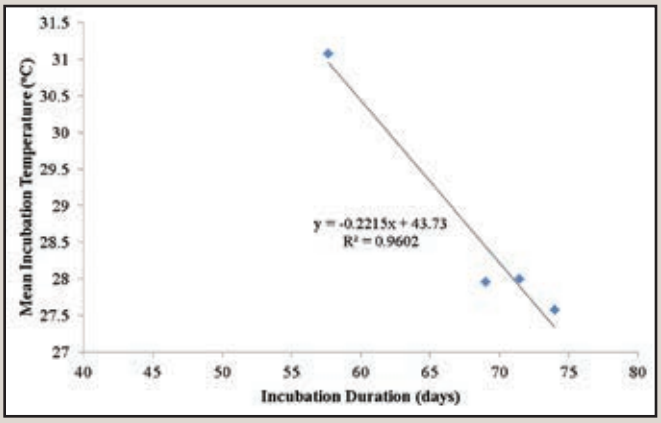

FIG. 2. Incubation duration as a relation of the mean incubation temperature for four *Uma rufopunctata* egg clutches. Note: Clutch #4 was not included as the only egg that was incubated from this clutch died immediately after hatching for unknown reasons; incubation length of clutch #4 was 69 days and mean incubation temperature was 27.6°C.

filled with an 8:1 sand:water mixture and the other was filled with a 16:1 sand:water mixture. Nest boxes received supplemental heating from above via a 40 W radiant heat bulb on 24 h/day. Boxes were weighed weekly and lost water weight was added back to maintain specific saturation levels. Animals were rotated off exhibit, one pair at a time, to allow for known lineage and breeding of multiple animals throughout the year. Copulation was observed on 3 July 2013. Male-male combat was observed among all three males on 12 November 2013 when all males were separated from females and housed together off exhibit while animals were cooled over the winter (Tietgen and Foster, unpubl.). One adult male had to be separated after several weeks due to weight loss and a small rostral abrasion. We now house all mature males separately.

Adult diet has included various invertebrates, such as crickets, roaches, mealworms, and waxworms, offered 4–5 times weekly. Crickets were gut-loaded with Zeigler® cricket diet and all prey was dusted with Repashy® Calcium Plus or TetraFauna Reptocal® reptile supplements. Because the species has been described as omnivorous (Stebbins 1985), a mixture of leafy greens and vegetables was also provided two times per week in addition to occasional natural browse. The lizards did not appear to eat salad mix or natural browse, however, preferring invertebrate food. Neither the exhibit nor the breeding enclosure contained standing water. Lizards were misted once per week to provide small regions of humidity.

This species has been very active in their enclosures and has proven to be an effective exhibit animal at the Zoo. When on exhibit, they have been reliably visible and often observed sand swimming only to re-emerge from beneath the substrate. They cohabitate well in mixed-sexed groups with little apparent aggression (although male-male aggression has been noted) or weight disparities that might indicate high levels of competition for food.

Adults.—Our 3.4 founder animals were less than one year of age when we received them, based on their masses at acquisition; mean (± 1 Standard Error [SE]) was 14.7 g (± 2.37). They were managed as a colony in the exhibit enclosure until our concentrated breeding efforts began in February 2013. At this point we marked them for individual identification with cattle markers (Baumer and Foster 2011) and took photographs of the unique bands on the ventral side of the tail for a secondary means of individual identification. Passive Integrative Transponders (PIT tags) have since also been placed in these animals as well.

Males have a greater SVL than females in other *Uma* species (Mayhew 1965; 1966a, b; Gadsen et al. 2006) and *U. rufopunctata* (Goldberg 2012). Mass of *Uma rufopunctata* had not been described previously. Mass of our adults was recorded on 9 April 2014, and males were significantly larger than females (mean mass [± 1 SE] = 46.1 g [± 1.40] and 28.5 g [± 1.28], respectively; p = 0.0003). Mass and SVL were recorded on 10 May (Fig. 1). Mass was correlated with SVL (r^2 = 0.9801). Both mass and SVL differed between sexes with males being larger in both measures (p = 0.0038 and p = 0.0024, respectively). Notably, one of the 2013 hatchlings had lost its tail, contributing to a lower mass to SVL ratio than would otherwise be expected.

Breeding.—Between 3 March 2013 and 22 September 2013, five clutches of fertile eggs were produced by three females through our managed breeding efforts. Breeding setups were designed without significant knowledge of nesting conditions of wild *Uma;* we therefore provided the thermal heater, deep nesting substrate, and two levels of saturation to allow females a variety of nesting conditions from which to choose. Females consistently deposited eggs in the 8:1 sand:water mixture. As a result, we modified breeding enclosures in 2014 to reflect this preference. Females consistently dug holes several days prior to oviposition and filled the nest hole after completing oviposition. Staff monitored the females closely once they began digging and were able to carefully excavate eggs post-oviposition. All eggs were laid on the bottom of the nest boxes, approximately 14 cm deep. One female developed eggs on exhibit, and was moved to the breeding enclosure with an established pair to nest several days prior to egg deposition on two occasions. These moves were performed to prevent reproductive complications as the exhibit did not offer nesting opportunities; the animal successfully nested on both occasions.

Eggs and incubation.—Mean (± 1 SE) egg clutch size was 3 (± 0.45); range 2–4. This is consistent with clutch sizes of preserved specimens (Goldberg 2012). We took the mass of four individual eggs from two separate clutches; mean was 1.925 g (± 0.165); range = 1.7–2.4 g. All eggs were placed in Suspended Incubation Method (S.I.M.) containers (Squamata Concepts LLC, Staten Island, New York; Baumer et al. 2012) in an Avey® RCAB200 Reptile Cabinet incubator for incubation. Clutches were incubated at 27–31°C with eggs hatching in 58–74 days (Fig. 2). Incubation duration was strongly correlated with mean incubation temperature with higher temperatures resulting in shorter incubation times (r^2 = 0.9537; Fig. 2). Of 14 viable eggs laid, 13 were incubated and one was damaged during excavation. Of the 13 eggs incubated, 10 hatched. The only egg produced from clutch 4 hatched, but the hatchling died immediately afterwards.

Hatchlings.—Mean mass of hatchlings was 2.3 g (± 0.08). All hatchlings were marked with cattle markers for individual recognition, as with the founders. Photographs of the ventral side of the tail were also taken for a secondary means of individual identification until the animals were large enough for placement of PIT tags.

Hatchlings were reared with siblings in glass aquaria modeled after the adult enclosures. Sand substrate was used with large rocks for basking sites underneath an Exo Terra® 160-watt Solar Glo UV/heat bulb. Hatchlings were fed appropriately sized invertebrates 5–7x weekly for the first six months, after which

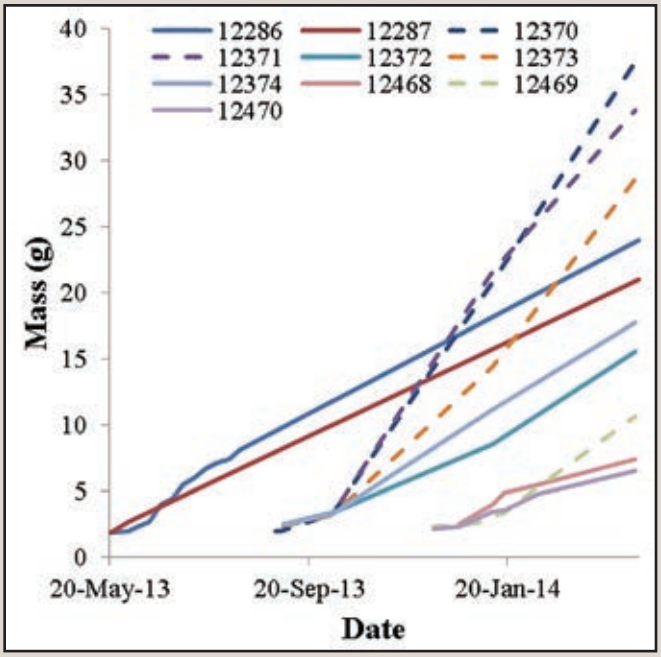

FIG. 3. Growth data of *Uma rufopunctata* hatched at the Phoenix Zoo; females are designated with solid lines and males with dashed lines. Clutch #1 (#12286 and 12287, females) hatched on 8 May 2013. Clutch #2 (#12370, male) hatched on 30 Aug 2013. Clutch #3 (#12371–74) hatched on 4–5 September 2013. Note: #12373 lost its tail and as a consequence has a lower mass than would be expected, but is still heavier than female clutch-mates. Clutch #5, animals #12468–12470 hatched on 4–5 December 2013. Note the more rapid growth rate of males.

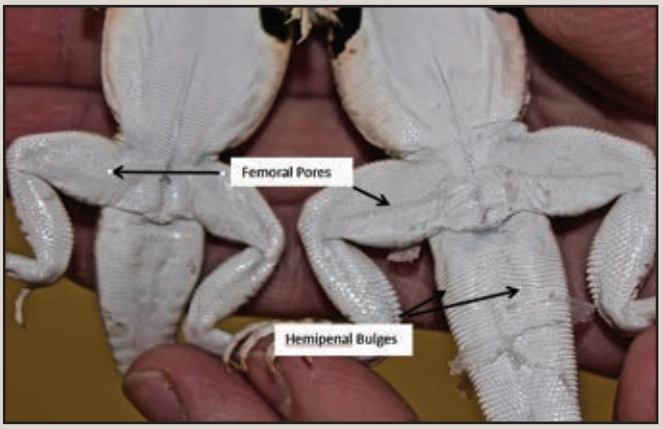

FIG. 4. Photograph comparing ventral side of a nine-month male (right) and thirteen-month female (left) *Uma rufopunctata* noting the more prominent femoral pores and hemipenal bulges of the male.

they were reduced to the adult diet of 4–5x weekly. Hatchlings cohabited well and food competition was minimal. A single animal lost 50% of its tail through a sudden event, although we cannot verify if this injury was caused by an encounter with another hatchling or a mishap involving the tank furniture.

Hatchling growth data were also recorded (Fig. 3). By just over half a year in age, the sex of hatchlings was easily determined. Males were larger than female clutch-mates at this age (Fig. 3), displayed more prominent striping, and had larger, more prominent femoral pores and hemipenal bulges (Fig. 4). On 8 Jan 2014, one of two juvenile females housed together laid infertile eggs at 8 months of age; weights of these animals were 14.4 and 18 g. Observations of *U. notata* by Mayhew (1966) predict that a small number of wild individual *Uma* may breed in the summer following hatching; the abundance of food in a captive setting will likely increase the number of individuals showing such early development.

Uma rufopunctata appears to be an easy-to-breed species under the conditions described above. Their unique adaptations, behaviors, natural history, and high activity levels, make them desirable exhibit animals for zoos. Additionally, this is an important native species to work with. Their small geographic range makes *U. rufopunctata* extremely vulnerable and they are threatened by habitat degradation and climate change (Bagne and Finch 2012).

We can apply what we have learned about captive propagation of *U. rufopunctata* to other fringe-toed lizard species including the endangered Coachella Valley Fringe-toed Lizard (*U. inornata*). This species is restricted to the Coachella Valley, Riverside Co., California, in an area less than 500 km^2. Here the entire species apparently occurs in fewer than five locations and the habitat quality and area, much like that of *U. rufopunctata*, is declining (Hammerson 2007). Our efforts to establish husbandry and breeding protocols for *U. rufopunctata* might allow this species to be a model for its endangered congener.

There is still much information to be gained about *U. rufopunctata* and other *Uma* species. As with many species occupying small geographic ranges in remote areas, much can be learned by working with fringe-toed lizards in captivity. Future research at the Zoo will attempt to investigate temperature-dependent sex determination in *U. rufopunctata*.

Acknowledgments.—We thank the Phoenix Zoo Herpetology Staff for all of their assistance. We also thank Tracy Ferrick, Richard Sartor, and Gary West for reviewing a previous version of this manuscript. We are grateful to Randy Babb of Arizona Game and Fish for donating these animals.

Captive Husbandry of the Arakan Forest Turtle (*Heosemys depressa*) and its Implications for Conservation

The Asian Turtle Crisis, officially identified in the late 1990s (Behler 1997), has resulted in the near or complete extinction of many species of turtle in Southeast Asia in the past few decades. Populations of Asian tortoises and freshwater turtles are under threat from a variety of human impacts including collection for local consumption, habitat degradation and loss, and most significantly, the regional and international trade for food, medicine, and the pet market. In the 1990s, this illegal trade brought in a minimum of 13,000 tons of live turtles each year (Van Dijk 2000). In recent years, the availability of chelonians has decreased as their populations have dwindled due to overwhelming collection pressures, which has increased the value of each turtle. This has brought emphasis to the pet trade, wherein endangered and foreign chelonians are the driving factors in purchases and owning one of these rare animals indicates social status in Asian cultures (Foley et al. 2012). Nonetheless, Asian chelonians continue to be removed from the wild at unsustainable rates.

Harvesting pressures are so extreme that conservation efforts to save some of these species exclusively in their home ranges may be unsustainable, and *ex situ* populations have arisen as crucial components for long-term conservation of chelonian biodiversity (Horne et al. 2011). The remote location and nature of many endangered turtle species' natural distribution, as well as the rapidity with which the Asian Turtle Crisis has taken place, has created a situation wherein conservation stakeholders have little information about these species' natural history, behavior, habitat preferences, and reproduction. These knowledge gaps present challenges to the development of captive and field conservation efforts. Through the interpretation of limited data on natural histories, regional climates and biomes, trial-and-error approaches, and scientific research, *ex situ* efforts are coming closer to reaching their full, and necessary, conservation potential.

TABLE 1. Clutch size and hatch rate for *Heosemys depressa* at Zoo Atlanta to date. Year of ovipositon is reported here; note that eggs hatched in following calendar year.

Year of ovipostion	Clutch size	# Hatched	% Success
2004 – Female 1	4	1	25%
2005 – Female 1	2	2	100%*
2006 – Female 1	4	2	50%
2007 – Female 1	4	2	50%
2008 – Female 1	4	0	0%
2009 – Female 1/2	9**/8	0/1	0%/12.5%
2010 – Female 2	6	4	66%
2011 – Female 2	4	1	25%
2012 – Female 2	8	1	12.5%
2013 – Female 2	8	5	62.5%

*The two offspring from 2006 (clutch laid in 2005), died within 60 days of hatching from yolk peritonitis. ** Female 1 died due to dystocia from clutch in 2009.

Heosemys depressa is an iconic example of a species severely affected by the Asian Turtle Crisis. The IUCN Red List has categorized the species as Critically Endangered and the species was ranked in the Top 25 Most Endangered Tortoises and Freshwater Turtles list in 2003 and 2007 and the top 30 in 2011 (Rhodin et al. 2011). Arakan Forest Turtles were thought to be extinct, with no live specimens observed for over 100 years, until biologists rediscovered the species in a Chinese food market in 1994 (Iverson and McCord 1997). They were not observed in the wild by biologists until the year 2000 (Platt et al. 2003). *Heosemys depressa* is not only rare in the wild, but also rare in captivity. As of August 2014, the Association of Zoos and Aquariums' regional studbook reported the captive population to consist of 24 males, 28 females, and 14 juveniles of unknown sex (24.28.14); of these, only 12.5.0 were wild-caught adults (B. Hughes, pers. comm.).

The natural history and geographic distribution of *Heosemys depressa* are poorly known, but summaries of the available information were provided by Platt and Myo Myo (2009) and Platt et al. (2003, 2010b). Arakan Forest Turtles are endemic to a small region of western Myanmar called the Rakhine Hills (formerly the Arakan Hills or Arakan Yoma [in Burmese yoma translates to hill]). Arakan Forest Turtles have been documented in the southern Rakhine Hills, within the Rakhine Yoma Elephant Range, and were recently found by biologists farther north in the southern Chin Hills (S. Platt, pers. comm.). This mountainous strip extends along the western coast of Myanmar and is characterized by high, steep parallel ridges separated by streams that flow within deep, restricted valleys. The habitat is composed mainly of thick bamboo (~75%) with large evergreen trees scattered throughout (Platt et al. 2010a). The climate is broken into three distinct seasons: a wet season brought on by the southwesterly monsoons occurring from June through October, a cool dry season from November to early February, and a hot dry season from late February to May (Platt et al. 2010b). The habitat preferences of *H. depressa,* according to interviews with local villagers and observations of Platt et al. (2010b), appears to be mainly dense bamboo forests, but they have also been observed in evergreen forests, deciduous forests, second-growth forests, and even sugarcane fields at elevations <500 m (Platt et al. 2003). Arakan Forest Turtles seem to be most active during the wet season and partially dormant during the drier months. They have been observed climbing hills roughly 60° steep and specimens have been found buried deep in forest leaf litter (Platt et al. 2010b).

These observations and natural conditions guide the perception and management techniques used to care for *Heosemys depressa* in captivity. Some of the key aspects of their husbandry are high humidity, constant access to a water source sufficiently large for soaking, proper diet, and annual cycling of adults for breeding. The following has been the approach to captive husbandry of this species at Zoo Atlanta. Considering situational variables such as spatial limitations, budget, and the climate of other areas, husbandry techniques may need modification from what is described here. The geographic location of Zoo Atlanta had significant implications for how the collection was managed. What has worked for us is probably not the only solution to successfully keeping and breeding *Heosemys depressa,* as there still is much to learn about caring for this poorly understood species.

SPECIMEN HISTORY AT ZOO ATLANTA

Zoo Atlanta acquired its first pair of *Heosemys depressa* in 2001. The male had a carapace length of 244 mm, width of 161 mm, and

PHOTO BY LUKE WYRWICH

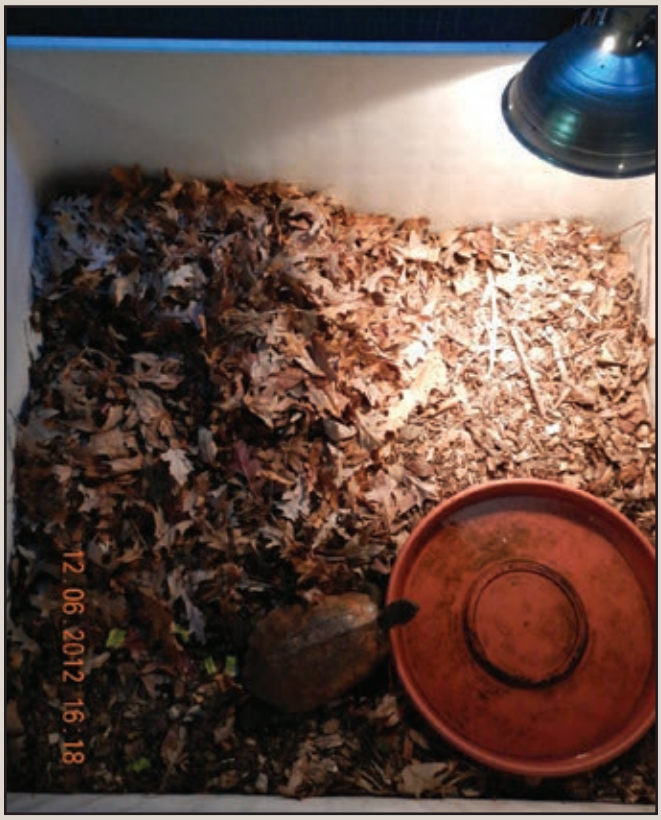

Fig. 3. Adult indoor enclosure. Note pile of leaves in upper left corner in which *Heosemys depressa* often burrowed for long periods.

Fig. 4. A) Adult in humid pile of leaves, a favorite pastime. B). Close-up view of adult in leaf pile. The turtle's head was usually all that was visible.

mass 2.25 kg. The female had a mass of 2.23 kg. We successfully bred this pair for the first time in 2004/2005 (Table 1). This female died in fall of 2009 due to breeding complications. We acquired an additional female in spring 2009 from Zoo Miami, which acquired her in 2001. She measured a carapace length of 232 mm, width of 164 mm, and a mass of 2.87 kg upon arrival at Zoo Atlanta. We have successfully bred her multiple times with our original male since 2009 (Table 1). An additional male was added to the collection in 2011, which has not yet been in a breeding situation. This male had a carapace length of 228 mm, width of 159 mm and a mass of 1.84 kg. Of the 19 offspring produced thus far, 17 were alive and well at the time of writing (August 2014). The two offspring from 2006 (clutch laid in 2005), died within 60 days of hatching from yolk peritonitis.

Housing, Temperature, and Humidity

Outdoors.—Animals were kept outside during the warmer months of the year typically from April through October. The typical low-temperature threshold for keeping adults outside was 10°C at night, but they have been exposed to temperatures in the 4.4–9.4°C range when the following day forecasted highs of 21–26°C. Hatchlings and juveniles were not pushed to these extremes and were transferred indoors when the night time low was ~13°C.

Our adult pair of *H. depressa* was maintained in an enclosure measuring 3 x 5 m (Fig. 1), and one adult male was kept individually in an enclosure measuring 2.4 x 3 m. Larger juveniles (2 years or older) were kept in enclosures that measured 1.2 x 1.2 m or larger. Smaller juveniles (2 years old or younger) and hatchlings (after yolk was absorbed) were kept in enclosures that were 0.6 x 1.2 m with a screen top to prevent predation (Fig. 2). Arakan Forest Turtles have proven to be great climbers and their ability to escape should not be under-estimated. A screen top or an overhang should be used at the top of enclosure walls to make them secure.

Table 2. Egg masses and dimensions for *Heosemys depressa* at Zoo Atlanta in 2013. Measurements recorded 33 days after oviposition.

Egg	Mass (g)	Length (mm)	Width (mm)
1	54.2	68.52	35.99
2	57.0	64.66	37.68
3	51.9	68.19	35.31
4	35.4	63.67	35.13
5	49.7	63.60	35.38
6	51.8	63.63	36.19
7	47.8	61.14	35.77
8	48.0	63.75	34.49

Ambient temperature and humidity were subject to the local weather conditions in Atlanta. Temperatures normally ranged from 10–38°C while turtles were outside. For the majority of the time spent outside, day-time highs were 29–36°C. Enclosures were placed in a shady area to mediate high temperatures, which also simulated their natural habitat of bamboo forests. Atlanta's hot summers also bring high humidity, which seemed to be

Table 3. Incubation temperature, length, and hatchling morphometrics for *Heosemys depressa* at Zoo Atlanta in 2014.

Egg #	Incubation temperature (°C)	Incubation time (days)	Measurements recorded (days post-hatching)	Weight (g)	Carapace width (mm)	Maximum carapace length (mm)	Maximum plastron length (mm)
5	30	146	27	45.0	54.48	64.95	56.78
6	30	150	23	35.8	52.64	62.78	55.35
7	30	169	4	35.2	51.09	59.13	53.38
8	30	171	2	35.1	51.09	59.66	55.60
3	26.1	174	26	50.3	57.99	68.26	61.86

Fig. 5. Indoor hatchling enclosure.

favored by *H. depressa*. In our facility, humidity was supplemented by a misting system with Rainbird® irrigation heads to maintain humidity during hotter and drier periods.

Indoors.—Adults were kept individually in enclosures ~1.2 x 1.2 m in a room that was maintained at ~21°C with low ambient humidity of about 40–50% (Fig. 3). The low humidity replicated the dry season that they would experience in their natural habitat. They were misted once or twice a week for about 10–60 seconds to induce feeding. Typically, adults ate little to nothing during their "dry" period indoors; this was observed especially with gravid females. Based on our observations, this dry period seems important for annual reproductive cycling and to induce courtship behaviors the following "wet" season. Older juveniles have also done well in this environment. Younger juveniles and hatchlings were kept in a room maintained at 21–26°C and with higher ambient humidity (60–80%). Lighting was used strategically to offer the individuals a thermal mosaic that included hot spots between 29–34°C for basking behavior. Zoo Atlanta specimens spent more than half of the year outdoors exposed to natural UVB, and consequently, they appeared to remain healthy with the use of regular (non-UVB emitting) fluorescent and incandescent bulbs for light and heat when they were indoors. If animals were only kept inside, they might benefit from use of full-spectrum bulbs that produce UVB.

Water source, Substrate, and Enclosure Furnishing

The large outdoor pens included ponds measuring ~1.2 x 1.8 m and 25 cm at their deepest point. These ponds were constructed with a gentle gradation, with one end being shallow (5 cm) to provide easy access. For adult indoor enclosures, a ~60-cm diameter plastic planter drip-catch saucer was used as a water source. For younger animals, smaller saucers were selected following the general rule that the diameter of the saucer be larger than the turtle for which it was intended.

Substrate for animals in large outdoor enclosures was not manipulated and consisted of natural soil. Indoor enclosures for adults were provided with a natural mulch substrate. Juveniles and hatchlings were maintained on a substrate composed of equal parts sand, sphagnum moss, leaves and three parts coconut fiber. Reproductive females were offered a ~20-cm layer of this substrate mix so they could excavate a nest, which usually occurred in November–December. This mix was designed to hold humidity, allow burrowing, and simulate the forest floor. Leaves were used to cover the entire land area of all enclosures.

A pile of leaves was provided in each enclosure, which acted as natural high humidity refugia (Fig. 4). For indoor setups, this pile was misted as needed to maintain high humidity within the pile (~70–95%). This created a microenvironment of high humidity that appeared to be critically important for health and proper shell growth. Based on our experience, this was arguably the most critical aspect of their husbandry. Other materials, such as sphagnum moss, could be utilized to attain a similar micro-environment. Turtles often spent a large period of time in these piles, sometimes continuously for several days. Similarly, it was observed that all of the *H. depressa* in the Arakan Forest Assurance Colony in Gwa, Myanmar, burrowed and remained hidden in a deep layer of leaf litter offered in their enclosures (K. Platt, pers. comm). Larger piles of leaves offered in adult enclosures outside were used to buffer exposure to colder temperatures. Other refugia favored by *H. depressa* included plastic hides, logs, and live plants.

Diet

Animals were offered salad twice weekly, which included coarsely chopped greens, diced tomatoes, soaked Mazuri

Tortoise Chow®, with finely processed vegetables and fruit. Greens consisted of collard greens, romaine lettuce, and bok choy. Vegetables included sweet potato, yellow squash, zucchini, carrots, green beans, butternut squash, and acorn squash. Fruit was offered sparingly and included cantaloupe, bananas, oranges, kiwi, and apples. These ingredients were mixed together thoroughly. A source of protein was almost always added to juvenile salads. Protein sources included mice, earthworms, and soaked Mazuri Crocodilian Chow®, Mazuri Aquatic Turtle Chow®, Nasco Turtle Brittle®, and/or Reptomin® sticks. Protein seemed to be less important for adults (offered once weekly) than for juveniles and was consequently used in moderation. In our experience, excessive protein often appeared to promote the development of large clutches that could have caused egg binding and death of the 2001 female. Mineral and vitamin supplements were added sparingly about once weekly and included the combination of Miner-all® and Vit-all® or Rep-Cal® Herptivite and Calcium with vitamin D3.

Reproduction

Breeding.—Sexes were maintained separately during their dormant period (~October–April), which appeared to be important for the annual reproductive cycle. Once conditions outside were appropriate in the Spring (see above), they were moved outside together where courtship behaviors and copulation started almost immediately. Rain (natural or artificial) almost always prompted courtship behaviors from the male. Reproductive events were observed most often early in this season and decreased in frequency as it continued.

Females typically laid eggs in November or December, although in one instance, eggs were laid in March. D. Lawson (pers. comm.) also observed this discrepancy in his collection. Females excavated holes about 10–15 cm into the substrate to oviposit and often dug test holes prior to oviposition. Usual clutch size was 2–6 eggs. In our experience, captive clutches larger than six have proven to be problematic, leading to serious health concerns for reproductive females. The clutch in 2013 had a mean mass of 49.48 g (Table 2).

Incubation.—Eggs were collected within 48 h of oviposition. Upon collection, the top of each egg was marked with a pencil to serve as a reference point to maintain its original orientation and prevent accidental rotation and death of the embryo. The eggs were then partially buried, with about half of the egg exposed, in a 1:1 ratio of coarse vermiculite to water by weight, in a covered plastic container measuring 20 x 28 x 13 cm. This egg box had one small hole in each side for air circulation and was placed in a large Nature's Spirit Reptiles® incubator. A bowl of water was used at the bottom of the incubator to ensure a high level of humidity throughout incubation. Typical incubation temperatures were 26.7°C for producing males and 28.8°C for producing females; 30°C was also used to produce females. Hatchlings were sexed endoscopically once reaching ≥ 80 g by Zoo Atlanta veterinary staff. Incubation time ranged from 117 to 173 days, with eggs incubated at higher temperatures hatching about a month earlier. One interesting note of development discovered when eggs were candled was that they did not show signs of development for the first several months of incubation. D. Lawson (pers. comm.) produced eggs of *H. depressa* consistently; however, his experiments with diapausing eggs to shorten incubation failed to produce viable offspring.

Hatchling husbandry.—Hatchlings were allowed to fully leave the egg before removal from the incubator. Their exposed yolk sacs were dipped in a dilute betadine solution to prevent infection. They were set up in a tank measuring ~50 x 25 x 30 cm with a thick layer of moist sphagnum moss and a shallow water source (Fig. 5). Hatchlings were not offered food for the first week and usually started feeding two or three weeks after hatching. Hatchlings were offered a salad as described above, but tended to prefer protein. Once their yolk sac was absorbed and plastron completely closed, they were transferred to a more naturalistic setting, similar to that of juveniles described above.

Discussion

What has been described here represents significant institutional development in husbandry techniques for the Arakan Forest Turtle and we continue our breeding program with our 2.1 adults. Though there has been considerable progress toward the captive conservation efforts for this enigmatic species, there is still a substantial amount to be accomplished. Zoo Atlanta's breeding success, measured through hatch rate, has ranged from 0–66 percent/clutch, leaving ample room for improvement. We are fine-tuning and adjusting our management techniques to create a more successful program. There undoubtedly is a need for additional field research on wild populations so we can learn more about the species' natural behaviors, preferences, and needs. This information from the field would impart scientific rigor to our efforts and techniques instead of being based on anecdotal experience. Observations and scientific studies of captive populations may also help us learn about difficult to observe aspects of the biology of this secretive species.

Acknowledgments.—We thank D. Lawson, R. Hudson, S. and K. Platt, and B. Anders for assisting in gathering field data and review of this manuscript. Additional thanks go to B. Hughes for information on the *H. depressa* studbook and the entire Zoo Atlanta Department of Herpetology for assisting in the development of husbandry techniques.

Cover Images for *Herpetological Review*

We are looking for photographic images to appear on future covers of *HR*. To be considered, preferred images should have the following qualities:

- Should be technically superior photographs (e.g., composition, lighting, etc., should be excellent; subject must be in focus).
- Should be taken in vertical format, or, if in landscape format, permit cropping to achieve a vertical orientation (2550 × 3300 ppi).
- Should be based on film or digital media; if the latter, the native resolution must be sufficiently high to permit cropping and/or enlargement to print publication quality.
- Preference will be given to images that depict poorly known species. These could include recently described taxa or species for which a color illustration has never been published.
- Preference will be given to images that communicate some aspect of the biology of the organism (e.g., predation, feeding, courtship, crypsis).
- Images should not have been published previously nor concurrently submitted for publication elsewhere (print or electronic media).

Images for consideration should be submitted as low-resolution jpg or pdf files. Do not send full resolution images unless requested to do so. All submissions or questions should be directed to the Editor (herpreview@gmail.com).

GEOGRAPHIC DISTRIBUTION

Herpetological Review publishes brief notices of new geographic distribution records in order to make them available to the herpetological community in published form. Geographic distribution records are important to biologists in that they allow for a more precise determination of a species' range, and thereby permit a more significant interpretation of its biology.

These geographic distribution records will be accepted in a **standard format** only, and all authors *must* adhere to that format, as follows: SCIENTIFIC NAME, STANDARD ENGLISH NAME if available (for the United States and Canada as it appears in Crother [ed.] 2012. *Scientific and Standard English Names of Amphibians and Reptiles of North America North of Mexico, with Comments Regarding Confidence in Our Understanding*. 7th ed. Herpetol. Circ. 39:1–92 [available from ssarbooks.com], for Mexico as it appears in Liner and Casas-Andreu 2008. *Standard Spanish, English and Scientific Names of the Amphibians and Reptiles of Mexico*. Herpetol. Circ. 38:1–162), LOCALITY (use metric for distances and give precise locality data, including lat/long coordinates in **decimal degrees** and cite the map datum used), DATE (day-month-year), COLLECTOR, VERIFIED BY (*cannot* be verified by an author; curator at an institutional collection is preferred), PLACE OF DEPOSITION (where applicable, use standardized collection designations as they appear in Sabaj Pérez [ed.]. 2013, *Standard Symbolic Codes for Institutional Resource Collections in Herpetology and Ichthyology: an Online Reference*, ver. 4.0, available at http://www.asih.org/) and CATALOG NUMBER (required), COMMENTS (brief), CITATIONS (brief and must adhere to format used in this section; these should provide a geographic context for the new record). Close with author name(s) in bold, capital letters (give name and address in full—spell out state or province names—no abbreviations, e-mail address after each author name/address for those wishing to provide it—e-mail required for corresponding author). Please include distance from nearest previously known record (provide a citation or refer to existing vouchered material to substantiate your report). If publishing specific locality information for a rare or endangered species has the potential to jeopardize that population, please consult with the Section Editor at time of record submission. If field work and/or specimen collection occurred where permits were required, please include permit number(s) and authorizing agency in the text of the note. Generally, this means that permit information should be included for any specimens COLLECTED. This is unnecessary for photo vouchers.

Some further comments. The role of the "Standard Names" lists (noted above) is to standardize English names and comment on the current scientific names. Scientific names are hypotheses (or at least represent them) and as such their usage should not be dictated by a list, society, or journal.

Additionally, this geographic distribution section does not publish "observation-only" records. Records submitted should be based on preserved specimens that have been placed in a university or museum collection (private collection depository records are discouraged; institutional collection records will receive precedence in case of conflict). A good quality photograph (print, slide, or digital file) may substitute for a preserved specimen. Photographic vouchers *must* be deposited in a university or museum collection along with complete locality data, and the photographic catalog number(s) must be included in the same manner as a preserved record. Before you submit a manuscript to us, check Censky (1988, *Index to Geographic Distribution Records in Herpetological Review: 1967–1986*; available from the SSAR Publications Secretary), subsequent issues of *Herpetological Review*, and other sources to make sure you are not duplicating a previously published record. The responsibility for checking literature for previously documented range extensions lies with authors. **Do not submit range extensions unless a thorough literature review has been completed.**

For reports concerning **introduced species**, it is important to note whether a population has become established or if the report represents an isolated occurrence, such as a released captive. Additionally, it will be helpful to include any information that establishes a timeline for the introduction, such as date of first observation.

Please submit any geographic distribution records in the **standard format only** to one of the Section Co-editors: **David C. Blackburn** (Africa and Europe), **Indraneil Das** (Asia, Australasia, South Pacific), **Jerry D. Johnson** (Mexico and Central America, including the Caribbean Basin), **Alan M. Richmond** (USA & Canada), or **Gustavo J. Scrocchi** (South America). Short manuscripts are discouraged, and are only acceptable when data cannot be presented adequately in the standard format. **Electronic submission of manuscripts is required** (as Microsoft Word or Rich Text format [rtf] files, as e-mail attachments)**.** Refer to inside front cover for e-mail addresses of section editors. A template for preparation of geographic distribution notes is available online at: http://ssarherps.org/wp-content/uploads/2014/07/GeoDistNotes_FormattingGuidelines.pdf.

Recommended citation for new distribution records appearing in this section is: Cabral, H., and A. Caballero. 2012. Geographic distribution: Paraguay, Departamento Central: *Pseudoeryx plicatilis*. Herpetol. Rev. 43:622.

CAUDATA — SALAMANDERS

***ANEIDES AENEUS* (Green Salamander)**. USA: GEORGIA: Chattooga Co.: Dirtseller Mountain (34.37°N, 85.47°W; WGS 84). 16 July 2013. Nate Thomas and Matt Elliott. Verified by N. Castleberry. Georgia Museum of Natural History (GMNH 50426). A second specimen, GMNH 50425, was found on Little Sand Mountain. Floyd Co.: Rocky Mountain (34.35°N, 85.29°W; WGS 84). 10 October 2012. Brett Tyler and Nate Thomas. Verified by N. Castleberry. GMNH 50166. Walker Co.: John's Mountain (34.61°N, 85.09°W;

WGS 84). 13 October 2012. Nate Thomas. Verified by N. Castleberry. GMNH 50427. New county records (Elliott 2008. *In* Jensen et al. [eds.], Amphibians and Reptiles of Georgia, pp. 158–160. University of Georgia Press, Athens, Georgia).

Until the discovery of the records reported herein, *Aneides aeneus* was known to occur only in the widely separated Blue Ridge and Cumberland Plateau physiographic provinces of Georgia (Elliott 2008, *op. cit.*). While conducting general biological and ecological inventories on Rocky Mountain two of us (BT and NT) encountered green salamanders in crevices of both cliff and boulder sandstone outcroppings. Rocky Mountain is in the Ridge and Valley physiographic province and far removed from the Cumberland Plateau to the northwest and the Blue Ridge to the northeast. This discovery spawned further searches for this species on other Georgia mountains within this province resulting in the additional Ridge and Valley records documented above. Ridge and Valley records do not exist from adjacent Alabama, but a record from Grainger County, Tennessee ca. 210 km north of the John's Mountain site in Georgia represents the nearest previously known Ridge and Valley record (Redmond and Scott 1996. Atlas of Amphibians in Tennessee. Misc. Publ. No. 12, Austin Peay State University. 94 pp.). These records suggest that the species may be more widespread in the southern portion of the Ridge and Valley and surveys in appropriate habitats within this province in Alabama and southern Tennessee are warranted.

BRETT TYLER, Georgia Department of Natural Resources, Game Management Section, 2592 Floyd Springs Road, Armuchee, Georgia 30105, USA; **NATE THOMAS**, **MATT J. ELLIOTT**, and **JOHN B. JENSEN,** Georgia Department of Natural Resources, Nongame Conservation Section, 116 Rum Creek Drive, Forsyth, Georgia 31029, USA (e-mail: john.jensen@gadnr.org).

***HEMIDACTYLIUM SCUTATUM* (Four-toed Salamander)**. USA: NORTH CAROLINA: McDowell Co.: Box Creek Wilderness, Vein Mountain Tract (35.55400°N, 81.96539°W, WGS 84), ~330 m elev. 24 March 2014. Christopher R. Wilson. Verified by Jeffrey C. Beane. North Carolina Museum of Natural Sciences (NCSM photographic voucher CRW 14-3). Two additional animals were found in the Box Creek Wilderness, Yonguskas Tract (NCSM photographic voucher CRW 14-4) and Thompson Tract (no voucher). New county records (Jeffrey C. Beane, NC State Museum of Natural Sciences, pers. comm.). All animals were females found tending egg clutches under moss at the edge of small temporary pools within forested seepage areas along drainages. These properties are owned by 130 of Chatham LLC, a private land conservation company.

CHRISTOPHER R. WILSON, Unique Places LLC, 9 Bradford Pl, Hendersonville, North Carolina 28791, USA; e-mail: critterfro@gmail.com.

***SIREN INTERMEDIA* (Lesser Siren)**. USA: TEXAS: Williamson Co.: San Gabriel River, TX Hwy 29 at low water bridge crossing, E of Georgetown (30.6459ºN, 97.5850ºW; WGS 84). 19 March 1995. Mike Bartley. Verified by David Cannatella. Texas Natural History Collections (TNHC 70530). New county record (Dixon 2013. Amphibians and Reptiles of Texas: with Keys, Taxonomic Synopses, Bibliography, and Distribution Maps. Texas A&M University Press, College Station, Texas. 447 pp.). Specimen previously collected and cataloged into the TNHC without permit information.

KELSEY HORNUNG, Texas Natural History Collections, The University of Texas at Austin, 10100 Burnet Road, PRC 176/R4000, Austin, Texas 78758-4445, USA; e-mail: kelshorn@yahoo.com.

ANURA — FROGS

***ANAXYRUS (= BUFO) WOODHOUSII* (Woodhouse's Toad)**. USA: TEXAS: Madison Co.: Midway, 3 mi SE (30.9892ºN, 95.7286ºW; WGS 84). 2 May 1953. W. F. Blair. Verified by Travis J. LaDuc. Texas Natural History Collections (TNHC 35880). New county record (Dixon 2013. Amphibians and Reptiles of Texas: with Keys, Taxonomic Synopses, Bibliography, and Distribution Maps. Texas A&M University Press, College Station, Texas. 447 pp.). Specimen previously collected and cataloged into the TNHC without permit information.

KELSEY HORNUNG, Texas Natural History Collections, The University of Texas at Austin, 10100 Burnet Road, PRC 176/R4000, Austin, Texas 78758-4445, USA; e-mail: kelshorn@yahoo.com.

***ELEUTHERODACTYLUS PLANIROSTRIS* (Greenhouse Frog)**. PHILIPPINES: LUZON ISLAND: METRO MANILA: Quezon City, Barangay Mariana (14.618889°N, 121.033056°E; WGS84). 4–9 July 2014. Emerson Y. Sy and Benjamin Eleazar III; Quezon City, Barangay San Antonio (14.64814°N, 121.01459°E; WGS 84). 28 July 2014. Ronald Achacoso. Quezon City, Barangay Diliman (14.65408°N, 121.04819°E, WGS 84). 7 August 2014. Emerson Y. Sy and Benjamin Eleazar IIII. Verified by Fred Kraus. SVL 18.40–23.90 mm. National Museum of the Philippines (Field # EYS 343–348; EYS 352–353). First records for Luzon Island and second known locality for the Philippines. Eight individuals and clutch of eggs collected from three separate localities in a highly populated urban city. Two specimens found inside potted bromeliad plant (Bromeliaceae) and five specimens within a landscaped garden of residential house. A clutch of 15 eggs found under leaf litter in residential garden. One adult female frog found under wooden plank within public park with ornamental plant market stalls. This species is native to the Caribbean Basin, and was first documented in Southeast Asia on Mindanao Island (Olson et al. 2014. Herpetol. Rev. 45:652–653).

EMERSON Y. SY (e-mail: emersonsy@gmail.com), **BENJAMIN ELEAZAR III**, Philippine Center for Terrestrial and Aquatic Research, 1198 Benavidez Street, Unit 1202, Sta. ***ELEUTHERODACTYLUS PLANIROSTRIS* (Greenhouse Frog)**. PHILIPPINES: NEGROS ISLAND: NEGROS OCCIDENTAL: Bacolod City, Barangay Villamonte (10.67666°N, 122.96150°E; WGS84). 4 September 2014. J. C. Martyr. Verified by Fred Kraus. National Museum of the Philippines (Field # EYS 387–EYS 388). Adult female (SVL 22.75 mm) and clutch of eight eggs collected in residential garden. First record from Negros Island. Introduced species in the Philippines, recently recorded on Mindanao and Luzon (Olson et al. 2014. Herpetol. Rev. 45:652–653; Sy et al. 2015. Herpetol. Rev. 46: this issue)

EMERSON Y. SY (e-mail: emersonsy@gmail.com), **JOHN CLIFTON MARTYR**, Philippine Center for Terrestrial and Aquatic Research, 1198 Benavidez Street, Unit 1202, Sta. Cruz, Manila, Philippines; **ARVIN C. DIESMOS**, Herpetology Section, Zoology Division, National Museum of the Philippines, Padre Burgos Avenue, Ermita 1000, Manila, Philippines (e-mail: arvin.diesmos@gmail.com).

***GASTROPHRYNE CAROLINENSIS* (Eastern Narrow-mouthed Toad)**. USA: MISSOURI: Cape Girardeau Co.: Juden Creek Conservation Area, 4.1 km NNE of Cape Girardeau (37.339195, 89.497261; WGS 84). 6 September 2014. E. J. Kessler. Verified by C. A. Phillips. Illinois Natural History Survey (INHS 2014af, photo voucher). New county record (Daniel and Edmond 2014. Atlas of Missouri Amphibians and Reptiles for 2013. <http://atlas.moherp.org/pubs/atlas13.pdf>). Single specimen found under log in woods at the top of a bluff.

ETHAN J. KESSLER, Illinois Natural History Survey, Department of Natural Resources and Environmental Sciences, University of Illinois at Urbana-Champaign, Illinois, USA; e-mail: ekessle2@illinois.edu.

***INCILIUS (= BUFO) NEBULIFER* (Gulf Coast Toad)**. USA: TEXAS: Erath Co.: Tarleton State University, Stephenville, Texas (32.216621°N, 98.220934°W; WGS 84). 18 September 2014. Jacob D. Owen and Colt Hamilton. Verified by Carl Franklin. Amphibian and Reptile Diversity Research Center (UTA A-63146). New county record (Dixon 2013. Amphibians and Reptiles of Texas: with Keys, Taxonomic Synopses, Bibliography, and Distribution Maps. Texas A&M University Press, College Station, Texas. 447 pp.). Individual (16.4 g) found on Tarleton State University grounds at 0615 h on concrete sidewalk after a rainstorm. Specimen was collected under a Texas Parks and Wildlife Hunting Permit issued to Jacob D. Owen (#776440018849).

JACOB D. OWEN (e-mail: jacob.owen@go.tarleton.edu) and **COLT HAMILTON**, Department of Biological Sciences, Tarleton State University, Box T-0100, Stephenville, Texas 76402, USA (e-mail: gamingninja@ymail.com).

***INCILIUS OCCIDENTALIS* (Pine Toad)**. MÉXICO: HIDALGO: Municipality of Metztitlán: Reserva de la Biosfera Barranca de Metztitlán near Acalometlán (20.46984ºN, 98.67137ºW; WGS 84), 1306 m elev. 8 October 2011. René Flores Vargas. Verified by Irene Goyenechea. Colección Herpetológica Fotográfica, Centro de Investigaciones Biológicas, Universidad Autónoma del Estado de Hidalgo (CH-CIB 04, photo voucher). First municipality record and first record for Reserva de la Biosfera Barranca de Metztitlán. This specimen represents a range extension of 35.57 km NW from closest known, but unnamed locality in the Municipality of Agua Blanca de Iturbide (Ramírez-Bautista et al. 2010. Lista Anotada de los Anfibios y Reptiles del Estado de Hidalgo, México. Univ. Autón. Est. de Hidalgo, CONABIO. 104 pp.). The toad was found in the morning under a rock on the bank of Río Venados, surrounded by desert scrub habitat.

LEONARDO FERNÁNDEZ BADILLO (e mail: cyrtopsis@hotmail.com), and **RENE FLORES VARGAS**, Centro de Investigaciones Biológicas, Universidad Autónoma del Estado de Hidalgo, km 4.5 carr. Pachuca-Tulancingo, Mineral de la Reforma, Hidalgo, México.

***PHRYNOBATRACHUS OGOENSIS* (Ogooué River Frog)**. GABON: OGOOUÉ-IVINDO PROVINCE: Buffer Zone of Lopé National Park, Ramba Village (00.3635°S, 11.7872°E; WGS 84), 220 m elev. 6 June 2013. J. G. Larson. Verified by J. Rosado. Museum of Comparative Zoology (MCZ A-149217). Identification was made via comparison to the original species description (Boulenger 1906. Annali del Museo Civico di Storia Naturale di Genova. Serie 3, 2:157–172) and a topotype (MCZ A-14831). Mitochondrial data from 16S ribosomal DNA (GenBank Accession KP247505), the first genetic data for this species, was compared to all other known species of *Phrynobatrachus* for which comparable genetic data exist and was at minimum 6.19% divergent. This is the first record of this species outside of the type locality "Lambarene, Ogowe," in west-central Gabon, extending the known range approximately 175 km E. It is also the first record of this species in the vicinity of a protected area of Gabon, suggesting that this species is also found within the Lopé National Park boundaries. A single gravid female was collected from leaf litter in secondary forest. The specimen was collected under permits from Centre National de la Recherche Scientifique et Technologique (CENAREST; AR0013/13), Agence Nationale des Parcs Nationaux (ANPN; AE130014) and Direction de la Faune et de la Chasse (82/DGFAP).

JOANNA G. LARSON, Department of Ecology and Evolutionary Biology, Museum of Zoology (UMMZ), University of Michigan, 1109 Geddes Avenue, Ann Arbor, Michigan 48109, USA (e-mail: jglarson@umich.edu); **BREDA M. ZIMKUS**, Department of Organismic and Evolutionary Biology, Museum of Comparative Zoology, Harvard University, 26 Oxford Street, Cambridge, Massachusetts 02138, USA (e-mail: bzimkus@oeb.harvard.edu).

***PIPA CARVALHOI* (Carvalho's Suriname Toad)**. BRAZIL: RIO GRANDE DO NORTE: Municipality of Santa Maria: Agreste region, 60 km W Natal (5.854°S, 35.701°W; WGS 84), 137 m elev. 13 June 2014. Jaqueiuto Jorge. Verified by U. Caramaschi. Coleção Herpetológica da Universidade Federal do Rio Grande do Norte, Natal, Rio Grande do Norte, Brazil (UFRN 4142, 4143). Two adult males (UFRN 4142: 30.65 mm SVL, UFRN 4143: 30.46 mm SVL) collected in pond near a rock outcrop. Municipality of Tenente Laurentino Cruz: Seridó region, 170 km W Natal (6.157°S, 36.731°W; WGS 84), 703 m elev. 13 July 2014. Marcelo Kokubum. Verified by U. Caramaschi. UFRN 3457. Adult female (49.51 mm SVL) collected in a pitfall trap in the Caatinga region. This species is only known from the Brazilian states of Pernambuco, Ceará, Paraíba, Bahia, Sergipe, Minas Gerais and Espírito Santo (Miranda-Ribeiro 1937. O campo 1937:54–56; Myers and Carvalho 1945. Boletim do Museu Nacional do Rio de Janeiro, Nova Série Zoologia 35:1–24; Arzabe 1999. Revista Brasileira de Zoologia 16:851–864; Silvano and Pimenta 2003. *In* Prado et al. [eds], Corredor de Biodiversidade da Mata Atlântica do Sul da Bahia. CD-ROM, IESB/CI/CABS/UFMG/UNICAMP, Ilhéus; Vieira et al. 2007. Oecologia Brasiliensis 11:383–396; Silva et al. 2010. Check List 6:451–453; Santana et al. 2014. Check List 10:407–408). First state record extending the distribution of the species ca. 160 km NE from the Municipality of Boa Vista, Paraíba (Vieira et al. 2007, *op. cit.*) for Santa Maria and ca.120 km NW to Tenente Laurentino Cruz, closing a gap in the distribution of the species. Specimens were collected under permits issued by SISBIO/ICMBio (#12734-1).

JAQUEIUTO S. JORGE (e-mail: queilto@yahoo.com.br) and **ELIZA M. X. FREIRE**, Laboratório de Herpetologia, Departamento de Botânica e Zoologia, Centro de Biociências, Universidade Federal do Rio Grande do Norte, Campus Universitário, Lagoa Nova, CEP 59072-970, Natal, Rio Grande do Norte, Brazil; **MARCELO N. DE C. KOKUBUM**, Laboratório de Herpetologia, Unidade Acadêmica de Ciências Biológicas e Programa de Pós-graduação em Ciências Florestais/CSTR, Universidade Federal de Campina Grande, CEP 58704-300, Patos, Paraíba, Brazil (e-mail: mnckokubum@gmail.com).

***PIPA PIPA* (Surinam Toad)**. BRAZIL: CEARÁ: Municipality of Fortaleza: Açude Itaperi (3.791714°S, 38.554821°W; WGS 84). 20 January 2014. K. S. Serra. Verified by P.S. Bernarde. Coleção Herpetológica da Universidade Federal do Ceará, Fortaleza, Ceará, Brazil (CHUFC A 6749). This species was previously known from basins of Amazonian biome (Suriname, Guyana, Venezuela, Colombia, Ecuador, Peru, Bolivia and Brazilian Amazon) and the states of Mato Grosso and Goiás in Brazil (Alves-Pinto et al. 2014.

Herpetol. Notes 7:347–353). First state record and extends the known distribution ca. 890 km airline E from Canindé Municipality, Pará, Brazil and ca. 1.650 km airline NE from Bonópolis Municipality, Goiás, Brazil. This species is not native from Ceará and the introduction probably results from an illegal animal commerce that occurs in 2 km around Açude Itaperi. We also saw four other animals in the same place, but they were not captured. The connection of the Açude Itaperi with other lagoons suggests that the species occurs in other waterbodies in the Municipality of Fortaleza. Specimen collected under an approved ICMBio permit (42737-1).

KALYL SILVINO SERRA (e-mail: kalyl_bio@yahoo.com.br), **LUCAS BARROS DE CASTRO CRUZ**, **BRUNO ARAÚJO MARTINS**, and **GIOVANNA SOARES ROMEIRO RODRIGUES**, Universidade Estadual do Ceará (UECE), Laboratório de Ornitologia e Sistemática Animal (LORNISA), Av. Monsenhor Tabosa, s/n, CEP. 62.500-000, Itapipoca, Ceará, Brazil (e-mail: daniel.cassiano@uece.br).

***PRISTIMANTIS OCKENDENI* (Carabaya Robber Frog)**. BRAZIL: AMAPÁ: Municipality of Serra do Navio: Parque Natural Municipal do Cancão (0.913889°N, 51.999778°W; WGS 84), 120 m elev. 22 April 2012. Yuri B. Silva e Silva. Verified by A.P. Lima. Colecao Universidade da Universidade Federal do Amapá, Macapá, Amapá, Brazil (CECCAMPOS 170). *Pristimantis ockendeni* is an arboreal and nocturnal frog found in primary and secondary forests throughout the upper Amazon Basin of Peru, Ecuador, southern Colombia and northern Bolivia (Padial et al. 2004. Graellsia 60:167–174; http://research.amnh.org/herpetology/amphibia/index.html, 20 January 2014). In Brazil, this species was previously known from two states: Acre and Amazonas (http:// www.iucnredlist.org; accessed 30 December 2013). Two adult males were found (one collected) in an upland forest during the night on leaves of shrubs at 1–2 m of height. First state record, extending the range 986 km NW from the Manaus, Amazonas. Specimen collected under ICMBio/SISBIO permit #32651-1.

YURI B. SILVA E SILVA (e-mail: yuribreno2@gmail.com), **CARLOS E. COSTA-CAMPOS, DANIEL S. SOUSA VALENTIM**, and **MAYARA F. M. FURTADO**, Laboratório de Herpetologia, Departamento de Ciências Biológicas e da Saúde, Universidade Federal do Amapá, Campus Marco Zero, 68.903-419, Macapá, AP, Brazil.

TESTUDINES — TURTLES

***CHRYSEMYS DORSALIS* (Southern Painted Turtle)**. USA: ALABAMA: Bullock Co.: shallow floodplain swamp where Lockhart Creek crosses Highway 51 west of Hurtsboro, Alabama (32.229173°N, 85.463266°W; WGS 84). 27 September 2014. R. Birkhead, M. Birkhead, and S. Birkhead. Auburn University Natural History Museum (AUM 40826). Verified by David Laurencio. New county record; verified records are lacking for many Alabama counties (Mount 1996. The Reptiles and Amphibians of Alabama. University of Alabama Press, Tuscaloosa, Alabama. 347 pp.; www.vertnet.org, 29 Sept 2014). *Chrysemys dorsalis* is assumed to occur primarily in the western portion of the state extending eastward along the Alabama and Tallapoosa River where they intergrade with *C. p. picta*. A previous specimen (AUM 8920) collected from western Bullock County was personally examined by RDB and found to have large yellow blotches on the head and is lacking a dorsal stripe on the carapace but with alternating costal and vertebral seams on the carapace and therefore aligns more closely to *C. p. picta*. This specimen also represents the first record for *C. dorsalis* occurring below the Fall Line from the Chattahoochee drainage (Cowikee Creek). Adult female (126 cm carapace length, straight line) caught in baited ProMar collapsible funnel trap. Specimen was collected under AL General Scientific Collecting Permit #2014063841468680 issued to RDB.

ROGER D. BIRKHEAD, COSAM Outreach, Alabama Science In Motion, Auburn University, Alabama 36849-5414, USA (e-mail: birkhrd@auburn.edu); **CHELSEA K. WARD**, Department of Biological Sciences, Auburn University Montgomery, PO Box 244023, Montgomery, Alabama 36124-4023, USA.

***TRACHEMYS ORNATA* (Ornate Slider)**. MÉXICO: GUERRERO: Municipality of Zihuatanejo: Ciclopista Playa Linda, 4 km NW of Ixtapa (17.6844°N, 101.6310°W; WGS 84), 16 m elev. 12 July 2008. William H. Mertz. Verified by Edmundo Pérez Ramos. Amphibian and Reptile Diversity Research Center, University of Texas at Arlington (UTADC 3699, photo voucher). New municipality record, extending its range in the state ca. 200 km NW from the vicinity of Acapulco (Iverson. 1992. A Revised Checklist with Distribution Maps of the Turtles of the World. Privately printed, Richmond, Indiana. 363 pp.; Fritz et al. 2011. J. Zool. Syst. Evol. Res. 50:125–136), and also bridges a distributional gap between Acapulco area populations and those at Cabo Corrientes, Jalisco (Legler and Vogt 2013. The Turtles of Mexico: Land and Freshwater Forms. University of California Press, Berkeley, California. 402 pp.). The turtle was photographed during the morning in a mangrove swamp.

SQUAMATA — LIZARDS

***ASPIDOSCELIS SEXLINEATA* (Six-lined Racerunner)**. USA: ALABAMA: Bullock Co.: Wehle Forever Wild Tract, 6.4 km SE of AL Hwy 51 and Bullock CR 47 (Pleasant Hill Road) intersection (32.03176°N, 85.46720°W; WGS 84). 27 April 2014. J. Trent and E. Soehren. Verified by David Laurencio. Auburn University Museum of Natural History (AUM AHAP-D 857, digital photo voucher). New county record (Mount 1975. The Reptiles and Amphibians of Alabama. Agricultural Experiment Station, Auburn University, Alabama. 347 pp.). Male incidentally captured in permanent snake box trap placed within fire-maintained open pine sandy upland characterized by diverse herbaceous ground cover. Specimen photographed and released. Record fills gap within all surrounding counties in the eastern portion of the upper Coastal Plain region (Mount 1975, *op. cit.*) and was vetted through examination of online museum holdings (VertNet, HerpNET) and literature review.

JOHN A. TRENT (e-mail: john.trent@dcnr.alabama.gov) and **ERIC C. SOEHREN**, Elhew Field Station, Wehle Land Conservation Center, State Lands Division, Alabama Department of Conservation and Natural Resources, 4819 Pleasant Hill Road, Midway, Alabama 36053, USA (e-mail: eric.soehren@dcnr.alabama.gov).

CNEMIDOPHORUS CRYPTUS. BRAZIL: ESPÍRITO SANTO: Municipality of Viana: 900 m W of Viana, SW of BR 262 (20.388611°S,

40.50815°W; WGS 84), 30 m elev. April 2009. J. C. F. Oliveira, E. Pralon, and L. Novaes Venerano. Verified by M. S. Hoogmoed. Museu Paraense Emilio Goeldi, Belém, Pará, Brazil (MPEG 31482–31492). RIO DE JANEIRO: Municipality of Rio de Janeiro: Rio de Janeiro Galeão International Airport (22.8000°S, 43.2333°W; WGS 84), 6–40 m elev. No collecting date. Carlos Rodrigo Meirelles Abreu. Verified by A. Silveira. Museu Nacional Rio de Janeiro, Universidade Federal do Rio de Janeiro (MNRJ 21540). Species known from Venezuela, and northern and eastern Amazonia. In Brazil, the species occurs in the states of Amazonas, Roraima, Pará, and Amapá (Ávila-Pires 1995. Zool. Verh. Leiden 299:1–706; Mesquita and Colli 2003. Copeia 2003:285–298; Mesquita et al. 2006. S. Amer. J. Herpetol. 1:61–71). First record of the species in southeastern Brazil, approximately 3700 km from the southernmost known distribution of this species. In Espírito Santo the population seems to be well established due to the presence of newborns. In Rio de Janeiro only one individual was recorded and collected by chance during fieldwork. It probably represents an isolated occurrence. These records probably constitute invasions, likely human-induced, but at this time it is not possible to determine when the introduction occurred. Specimens from the Municipality of Viana were collected under a SISBIO permit (#20007).

S. ÁVILA-PIRES**, Coordenação de Zoologia, Museu Paraense Emílio Goeldi, C.P. 399, CEP 66017-970, Belém, PA, Brazil.

HEMIDACTYLUS TURCICUS **(Mediterranean House Gecko).** USA: CALIFORNIA: Orange Co.: La Habra (33.939652°N, 117.935443°W; WGS 84), 123 m. elev. 14 September 2014. Aaron Wells and Francisco Torres. Natural History Musem of Los Angeles County (LACM 186001, 186002). Verified by Neftali Camacho. New county record. Fills a gap for *H. turcicus* in southern California between San Diego and Los Angeles counties (Beaman et al. 2005. Herpetol. Rev. 36:79; Bernstein and Bernstein 2013. Herpetol. Rev. 44:474). Seven additional *H. turcicus* were collected at this site on 18 October 2014 by GBP, MHE, and REE (LACM 186003–186009). Two additional populations, E Bristol Lane at N Glassell Street, Santa Ana (LACM 186011–186015) and E Saint Gertrude Place at S Wright Street, Santa Ana (LACM 186017–186019), were also found. All three localities are more than 11 km from each other.

In total, four adult females, three adult males, and two juveniles were collected at the La Habra site, indicating an established population. The E Bristol Lane site in Santa Ana was first reported to the Herpetological Education and Research Project (http://www.naherp.com; HERP 124797, 128378) in September and October 2012, indicating geckos have been at this site for at least two years. Geckos were observed in a region spanning 240 m NNW to SSE and 130 m E to W. The broad spatial distribution, lengthy temporal occurrence, and range of size classes indicate that this is an established population. At the E Saint Gertrude Place at S Wright Street site in Santa Ana, geckos were observed in a region spanning 415 m N to S and 115 m E to W. Given this distribution and the various size classes observed, this population also appears to be established.

Sceloporus occidentalis were also observed at the La Habra and the E Bristol Lane sites. At the former site, *S. occidentalis* and *H. turcicus* were found within centimeters of each other using the same retreats (cracks in a cinder block wall). At the latter site, the two species were found in the same urban habitat (structures adjacent to a hedge row) ca. 25 m apart. Although the divergent diel activity periods likely reduce competition between these two species for some resources, these observations suggest they may compete for retreat space, at least in urban habitats. Their close proximity and co-occupation of retreats may also increase the chances for parasite and pathogen transmission. Specimens were collected under California Department of Fish and Wildlife Scientific Collecting Permit #SC4307.

GREGORY B. PAULY, Section of Herpetology, Natural History Museum of Los Angeles County, Los Angeles, California 90007, USA (e-mail: gpauly@nhm.org); **AARON WELLS**, 22918 Leonara Drive, Woodland Hills, California 91367, USA; **MAXWELL H. ESPINOZA**, 18942 Leadwell Street, Reseda, California 91335, USA; **THOMAS A. WAKE**, The Cotsen Institute of Archaeology and Department of Anthropology, University of California, Los Angeles, California 90095-1510, USA; **ROBERT E. HEMIDACTYLUS TURCICUS **(Mediterranean House Gecko).** USA: CALIFORNIA: Ventura Co.: Simi Valley, along N bank of Arroyo Simi, at confluence with Bus Canyon Drain, ca. 125 m N of intersection of Los Angeles Avenue and 5th Street (34.272817°N, 118.783861°W; WGS 84), 225 m elev. 3 October 2014. Christian Huntley. Verified by Neftali Camacho. Natural History Musem of Los Angeles County (LACM PC 1852). New county record extending the range of this species ca. 16.6 km W (airline) from the closest vouchered localities in Chatsworth, San Fernando Valley, Los Angeles County (Bernstein and Bernstein 2013. Herpetol. Rev. 44:474). Two adults were uncovered from deep (ca. 30 cm) leaf litter by day along the concrete-channeled stream terrace. A second, larger population (LACM 185981–185994) was also found.

Vouchered specimens include six adult females, four adult males, and four juveniles. These geckos were collected at night (2110–2300 h) from a commercial district along the exterior walls of concrete, stucco, or stone buildings, and along stone or brick retaining walls ca. 0–2 m off the ground. Most collection sites were illuminated by light fixtures attached to buildings and had minimal landscaping. The presence of adults and juveniles across a broad area suggests that this is an established population. Specimens were collected under California Department of Fish and Wildlife Scientific Collecting Permit #SC4307.

GILLIAN C. LARSON (e-mail: gillian.larson.102@my.csun.edu), **TANJA WOLFMEYER**, (e-mail: tanja.wolfmeyer.415@my.csun.edu), **BENJAMIN SINGH**, (e-mail: benjamin.singh.623@my.csun.edu), and **ROBERT E. PAULY**, Section of Herpetology, Natural History Museum of Los Angeles County, Los Angeles, California 90007, USA (e-mail: gpauly@nhm.org).

HEMIDACTYLUS TURCICUS **(Mediterranean Gecko).** USA: TENNESSEE: Knox Co.: On retaining walls adjacent to an office building and a commercial distribution facility in Knoxville (35.966133°N, 83.945117°W; WGS 84), ca. 300 m elev. 6 June 2014. Chase L. Hively, Joseph D. Prescott and J. Caleb Stair. David H. Snyder Museum of Zoology, Austin Peay State University (APSU 19503, 19504). Verified by A. Floyd Scott and Arthur C.

Echternacht. First vouchered record for Knox Co. Previously, an unverified observation of a single juvenile was made in Knoxville ca. 2.4 km E of the current location on 10 October 2012. The nearest previously verified record was made in Maryville, Tennessee ca. 24 km southwest of the current location on 17 August 2013 (Nordberg et al. 2013. J. Tennessee Acad. Sci. 88:64–66).

A total of 13 adult (3.8–5.5 cm SVL) specimens (6 males, 7 females) including one gravid female were observed from ca. 0030–0130 h suggesting the presence of an established population. Additional individuals have been observed at this location since the date of collection. Due to the close proximity of these individuals to a commercial distribution facility and a small garden, individuals may have arrived on shipping pallets and/or potted plants. The commercial distribution facility may also facilitate the dispersal of this species to new localities within and beyond Knoxville. Voucher specimens collected under a permit issued by the Tennessee Wildlife Resources Agency (#3812).

CHASE L. HIVELY, Department of Natural and Behavioral Sciences, Pellissippi State Community College, Knoxville, Tennessee 37933, USA; e-mail: clhively@pstcc.edu.

***IGUANA IGUANA* (Green Iguana)**. MÉXICO: SINALOA: Municipality of Ahome: San Miguel Zapotitlan, 5.8 km W of San Miguel Zapotitlán, 12.5 km N of Los Mochis (25.930472°N, 108.9991694°W; WGS 84), 17 m elev. 27 February 2013. Pedro Uriarte- Garzón. Verified by Adriana González-Hernández. Colección Nacional de Anfibios y Reptiles, Instituto de Biología, Herpetología–Referencia Fotográfica at Universidad Nacional Autónoma de México (CNAR IBH-RF 074 a–c, photo voucher). First municipality record, extending the known distribution 219 km airline N from the nearest known record at Costa Rica, Sinaloa, México (Smith and Van Gelder 1955. Herpetologica 11:145–149). The iguana was found in a tree (*Populus mexicana*) within riparian vegetation on the edge of Río Fuerte.

PEDRO URIARTE-GARZÓN (e-mail: uriartegp@hotmail.com) and **VÍCTOR HUGO-REYNOSO**, Colección Nacional de Anfibios y Reptiles, Departamento de Zoología, Instituto de Biología, Universidad Nacional Autónoma de México, Circuito Exterior s/n, Ciudad Universitaria, D.F., C.P. 04510, México.

***PHELSUMA LATICAUDA* (Gold Dust Day Gecko)**. USA: HAWAI'I: Kaua'i: Wailua: ~200 m SW of intersection of Hwy 56 and Hwy 580 at the south end of Wailua Road, which dead ends at the N bank of Wailua River (22.046414°N; 159.336929°W; WGS 84). 26 June 2014. Maxwell Hitchcock Espinoza and Robert E. Espinoza. Verified by Robert N. Fisher. Natural History Museum of Los Angeles County (LACM PC 1823, 1824, digital photographs of two individuals). First island record (McKeown 1996. A Field Guide to Reptiles and Amphibians in the Hawaiian Islands. Diamond Head Publishing, Los Osos, California. 173 pp.; Kraus 2009. Alien Reptiles and Amphibians, a Scientic Compendium and Analysis. Springer, Dordrecht. 563 pp.). Native to Madagascar and introduced and previously known from Hawai'i (Big Island), Maui, and O'ahu (McKeown 1996, *op. cit.*; Kraus 2009, *op. cit.*). Three adults and one juvenile observed at 1000 h along a wooden fence and on the trunk and adventitious roots of a *Pandanus* tree within 4 m of Wailua River. Several other adults and a juvenile were observed at 1630 h on the grounds of Kamokila Hawaiian Village, 5443 Kuamo'o Road, Wailua (22.043712°N, 159.360766°W) 2–3 m off the ground on *Pandanus* and other leafy ornamental vegetation. The different age classes and relatively high density of individuals at both localities suggests that breeding populations are well established.

MAXWELL HITCHCOCK ESPINOZA, 18942 Leadwell Street, Reseda, California 91335, USA (e-mail: maxwellhitch@gmail.com); **ROBERT E. ESPINOZA**, Department of Biology, California State University, Northridge, Northridge, California 91330-8303, USA (e-mail: robert.e.espinoza@csun.edu).

***PHRYNOSOMA DITMARSI* (Rock Horned Lizard)**. MÉXICO: SONORA: Municipality of Nacozari de García: Sierra de Nacozari, vic. Mina la Caridad, 1630 m elev. 15 September 2013. Timothy R. Burkhardt and Scott Trageser. Verified by T. J. Papenfuss. Museum of Vertebrate Zoology (MVZObs: Herp 13, 14; photographic voucher). First records for the municipality and the region between the Rio Moctezuma and Rio Bavispe; the closest documented locality is ca. 75 km SW of Cerro La Palma in the Sierra Baviacora (University of Arizona [UAZ] 39530–39543). The record also helps fill a range gap among the four previously documented populations: Sierra Manzanal (Lowe et al. 1971. J. Arizona Acad. Sci. 6:275–277), Sierra Baviacora (Lowe and Howard 1975. Southwest. Nat. 20:264–270), Rio Yaqui, vicinity of Tonichi (Perrill 1983. Herpetol. Rev. 14:123) and El Chorro, Municipality of Nácori Chico (Sherbrooke et al. 1998. Herpetol. Rev. 29:110–111). Both lizards, a male and juvenile, respectively, were observed at 0830 h on a steep and rocky south-facing hillside in a transition zone covered with a dense stand of Sinaloa thornscrub-Madrean oak woodland vegetation.

SQUAMATA — SNAKES

***ARIZONA ELEGANS* (Glossy Snake)**. USA: NEW MEXICO: Los Alamos Co.: DOE property; Pajarito Road, 2.25 mi W jct Pajarito Road and NM Hwy 4 (35.83603°N, 106.25773°W; WGS 84). 1 October 2014. Chuck Hathcock. Verified by Tom Giermakowski.

Museum of Southwestern Biology (MSB 95428). New county record (Degenhardt et al. 1996. Amphibians and Reptiles of New Mexico. University of New Mexico Press, Albuquerque, New Mexico. 431 pp.). Adult male DOR. Specimen was collected ca. 20 air mi NW of the nearest known locality.

CHUCK HATHCOCK, Los Alamos, New Mexico, USA (e-mail: chuckhathcock89@gmail.com); **CHARLES W. PAINTER**, 707 Griegos Road NW, Albuquerque, New Mexico 87107, USA (e-mail: cwpainter49@gmail.com).

***ARIZONA ELEGANS* (Glossy Snake)**. USA: TEXAS: Parker Co.: Soda Springs Road approximately 0.6 road mi. N of the I-20 frontage road (32.67349°N, 98.03993°E; WGS 84). 21 September 2014. E. Wostl, C. Roelke, and M. Fontenot. Verified by Carl Franklin. Amphibian and Reptile Diversity Research Center (UTA-R 62069). New county record (Dixon 2013. Amphibians and Reptiles of Texas: with Keys, Taxonomic Synopses, Bibliography, and Distribution Maps. Texas A&M University Press, College Station, Texas. 447 pp.). This locality is between the published ranges of the two recognized subspecies in the region. *Arizona e. elegans* is documented to the north and west and *A. e. arenicolor* has been documented to the east and south.

ELIJAH WOSTL (e-mail: ewostl@uta.edu) and **COREY E. ROELKE**, University of Texas at Arlington, Department of Biology, Box 19498, Arlington, Texas 76019, USA; **MALLORY L. FONTENOT**, 1315 West Abram Street, Arlington, Texas 76013, USA.

***BOIGA IRREGULARIS* (Brown Treesnake)**. USA: COMMONWEALTH OF THE NORTHERN MARIANA ISLANDS: Rota: Rota Seaport (14.136502°N, 145.135351°E; WGS84). 3 September 2014. Shelwyn Taisacan, Robert Ulloa. Verified by G. Zug. USNM 581745. Snake (42 g, 810 mm SVL, 1020 mm total length) captured in a mouse-baited trap hung on the fence perimeter of the Rota Seaport. Because the Northern Marianas Islands are historically snake-free, these traps are used around ports and airports for early detection of snakes that may stow away in vessels or aircraft from Guam (60 km to the south), possibly evading quarantine detections. Necropsy revealed no prey items in stomach or gastrointestinal tract. Dissection at USNM confirmed the snake was female. To our knowledge, this is the first incursion of a live *Boiga irregularis* on Rota. Brown Treesnakes previously observed on the island (N = 3) arrived in cargo already dead. The USGS Brown Treesnake Rapid Response Team mobilized 4 September–20 October 2014 to search the focal and surrounding areas for evidence of a possible incipient population; no additional snakes were found during this search effort.

***CROTALUS VIRIDIS* (Prairie Rattlesnake)**. USA: NEW MEXICO: Harding Co.: 2.25 km NNW of junction of NM-39 and US-54 in Logan, New Mexico (35.3903°N, 103.4228°W; WGS 84), 1190 m elev. 24 June 2007. Ian M. Latella and Howard Snell. Verified by J. Tomasz Giermakowski. Museum of Southwestern Biology (MSB 73141). New county record (Degenhardt et al. 1996. Amphibians and Reptiles of New Mexico. University of New Mexico Press, Albuquerque. 431 pp.). This record fills a distributional gap in northeastern New Mexico. This species is documented in adjacent Mora, Colfax, Union, San Miguel, and Quay counties (Degenhardt et al. 1996, *op. cit.*). Subadult specimen was found alive crossing NM-39 at 2221 h.

IAN M. LATELLA (e-mail: ilatella@unm.edu) and **HOWARD SNELL**, Museum of Southwestern Biology, MSC03 2020, 1 University of New Mexico, Albuquerque, New Mexico 87131, USA.

***HYPSIGLENA SLEVINI* (Slevin's Nightsnake)**. MEXICO: BAJA CALIFORNIA: Municipality of Ensenada: Sierra Santa Isabel, 2.41 km S of Puertecitos (30.327405°N, 114.648571°W; WGS84), 55 m elev. 14 June 2013. S. Murray. Verified by L. Lee Grismer. La Sierra University Digital Photograph Collection, Riverside, California (LSUDPC 9150–9151). Northernmost record for this species, extending the distribution 177 airline km NNW from Bahía de los Ángeles, Municipality of Ensenada, Baja California (Grismer 2002. Amphibians and Reptiles of Baja California, Including its Pacific Islands and the Islands in the Sea of Cortés. Univ. California Press, Berkeley, California. 399 pp.; Mulcahy and Archibald 2003. J. Herpetol. 37:566–571; Mulcahy et al. 2014. PLoS One 9:e97682). The snake was found surface active at 2205 h in an area comprised almost exclusively of volcanic rock; vegetation was dominated by Brittlebush (*Encelia farinosa*).

SAM MURRAY, 6312 Rancho Mission Rd. #327, San Diego, California- 92108, USA (email: samxmurray@gmail.com); **JACKSON D. SHEDD**, The Nature Conservancy, P.O. ***LAMPROPELTIS HOLBROOKI* (Speckled Kingsnake)**. USA: KANSAS: McPherson Co.: Maxwell Wildlife Refuge (38.482721°N, 97.458396°W; NAD 83). 18 September 2014. Daniel J. Martin. Verified by David J. Bender. University of Colorado Museum (UCM AC-186, photographic voucher). First documented record for this species in McPherson Co. (Collins et al. 2010. Amphibians, Reptiles, and Turtles in Kansas. Eagle Mountain Publishing, Eagle Mountain, Utah. 312 pp.). Nearest known records from adjacent counties include: Saline (37 km), Elsworth (47 km), Dickinson (62 km), Marion (45 km), and Harvey (46 km); no records are reported for Reno or Rice counties. A large (ca. >1 m) adult was found during a standardized reptile survey, basking at 1402 h in partial shade under a currant shrub (*Ribes* sp.) next to large stones in mixed-grass prairie. Maxwell Wildlife Refuge manager C. Peterson recalled observing *L. holbrooki* on the Refuge several times around 1999 but not since.

This observation was made as part of the Great Plains Reptile Monitoring Project (www.reptilemonitor.org), with funding and logistical support provided by the U.S. Fish and Wildlife Service, Colorado Parks and Wildlife, Texas Parks and Wildlife, and Colorado State Land Board through a State Wildlife Grant, and from Colorado State University and the U.S. Geological Survey. Work was conducted under Scientific Collection Permit No. SC-000-2014 (State of Kansas) and Colorado State University ACUC #13-4218A.

***OPHEODRYS VERNALIS* (Smooth Greensnake)**. USA: WISCONSIN: Vernon Co.: Township of Stark (43.606667°N, 90.629444°W, WGS 84). 16 October 2014. Terrell Beck. Verified by Joshua M. Kapfer (University of Wisconsin - Whitewater). Illinois Natural History Survey (INHS 2014ae, photo voucher). New county record. (Casper 1996. Geographic Distributions of the Amphibians and Reptiles of Wisconsin. Milwaukee Public Museum. 87 pp.). An individual adult was photographed basking on a gravel trail

on 16 October 2014 within the Kickapoo Valley Reserve on Star Valley Trail. Associated habitat consisted of old field successional vegetation. Adjacent habitats were a mix of agricultural fields and fallow fields of upland grass and shrubs. This observation complements a specimen collected by K. Teed on 28 July 1990 in Wildcat Mountain State Park (Milwaukee Public Museum, MPM 23475). The individual was found just off State Highway 33 on the road to the lower picnic area (T14N R02W, Sec. 14 NE4).

***PYTHON REGIUS* (Ball Python)**. USA: LOUISIANA: St. John the Baptist Parish: Town of Ruddock, Old Highway 51, 4.5 km S of Ruddock I-55 ramp (30.149723°N, 90.449167°W; WGS 84). 7 October 2014. Collected by Brian I. Crother and Mary E. White. Verified by David M. Sever. Southeast Lousiana University, Museum of Biology (SLU 02332, SLU-TC 1.78). First record for Louisiana (www.vertnet.org, accessed 10 October 2014; http://specifyportal.flmnh.ufl.edu/herps/, accessed 10 October 2014).

Python regius has been introduced in Florida via pet trade (Krysko et al. 2011. Zootaxa 3028:1–64). This species is known from many sites in Florida, with the closest previous record (UF 169730) being from the City of Pensacola (30.4194°N, 87.276389°W), approximately 309 km E of this first Louisiana record. Collection databases (Herpnet, Vertnet, and the FLMNH database) contain no record of *P. regius* from Alabama, Mississippi, or Texas. There is no evidence that *P. regius* is established in the state of Louisiana, although the species is thought to be established at a similar latitude and longitude in the Florida panhandle, despite a lack of direct evidence in the form of neonates or eggs (K. Krysko and L. Somma, pers. comm.). *Python regius* is known to occur in swamps (Luiselli and Angelici 2009. Ital. J. Zool. 65:183–185) and may be able to successfully overwinter in Louisiana because of its natural tendency to seek out burrows (Aubret et al. 2005. Evol. Ecol. Res. 7:743–758). This specimen is a sexually mature female (94 cm SVL) and appears to have been healthy. The digestive tract contains gray and brown hairs, some of which, at 2.9 cm, are too long to have come from a mouse or rat. Specimen collected DOR.

DANIELLE S. WASSERMAN (e-mail: danielleswasserman@gmail.com) and **BRIAN I. CROTHER**, Southeastern Louisiana University, Department of Biological Sciences, SLU 10736, Hammond, Louisiana 70402, USA (e-mail: bcrother@selu.edu).

***SIBON ANTHRACOPS* (Ringed Snaileater)**. PANAMÁ: Distrito Boquete: 200 m W Caldera (8.38868°N, 82.23274°W; WGS84), elev. 420 m. 16 July 2011. Jessica Van den Burgh. Verified by Jonathan A. Campbell. Amphibian and Reptile Diversity Resarch Center, University of Texas at Arlington (UTADC 7476, photo voucher). First record for Panamá, and extends the range ca. 200 km SW from the closest confirmed locality in Costa Rica (Província de San José, Pozos de Santa Ana [Solórzano 2004. Serpientes de Costa Rica/Snakes of Costa Rica, INBio, Santo Domingo de Heredia, Costa Rica. 792 pp.]).

***TANTILLA HOBARTSMITHI* (Smith's Black-headed Snake)**. USA: CALIFORNIA: Inyo Co.: Southeastern Argus Mountains, unnamed side canyon of Water Canyon (35.99036°N, 117.40489°W; WGS 84), 1150 m elev. 27 May 2014. Adam G. Clause. Natural History Museum of Los Angeles County (LACM 184721 [entire animal], TC 2082 [tissue], PC 1746–1747 [digital color photos]). New locality and second record from the Argus Mountains, ca. 26 km by air from the nearest known locality at Surprise Canyon, Panamint Mountains (Cole and Hardy 1983. Bull. Amer. Mus. Nat. Hist. 171:199–284; http://herpnet2.org; 11 June 2014). Northern Kingston Mountains, Crystal Spring (35.79444°N, 115.96178°W; WGS 84), 1160 m elev. 31 May–1 June 2014. Adam G. Clause. LACM 184750, TC 2090–2091, 2132, PC 1755–1756. New locality and third record from the Kingston Mountains, ca. 3 km by air from the nearest known locality of Smith Talc Mine, Kingston Mountains (HerpNET2, *op. cit.*). San Bernardino Co.: Southwestern Clark Mountains, Pachalka Spring (35.51806°N, 115.63064°W; WGS 84), 1500 m elev. 29 May 2014. Adam G. Clause. LACM PC 1788. First record from the Clark Mountains, ca. 37 km by air from the nearest known locality of Horse Thief Springs, Kingston Mountains (Cole and Hardy, *op. cit.*; HerpNET2, *op. cit.*). Northeastern San Bernardino Mountains, Hwy 18, 0.8 road km S of Cushenbury Springs (34.35591°N, 116.85161°W; WGS 84), 1320 m elev. 11 June 2013. Philip Clevinger. LACM 185113, PC 1799. First record from the San Bernardino Mountains, ca. 54 km by air from the nearest known locality of Long Canyon, Joshua Tree National Park (Cole and Hardy, *op. cit.*; HerpNET2, *op. cit.*).

All specimens verified by Gregory B. Pauly via examination of head color pattern and/or hemipene structure. Snakes discovered under stones or DOR, associated with spring-fed riparian zones. These records partially fill several gaps in the spotty, relic distribution of *T. hobartsmithi*. They increase the total number of published and/or museum-vouchered California localities for this species to 28 (Cole and Hardy, *op. cit.*; HerpNET2, *op. cit.*; Persons and Nowak 2006. Inventory of Amphibians and Reptiles at Death Valley National Park. USGS Southwest Biological Science Center, Flagstaff, Arizona. 47 pp.; Stebbins 2003. Western Reptiles and Amphibians 3rd ed. Houghton Mifflin Co., New York, New York. 533 pp.). Our work was approved under California Department of Fish and Wildlife Scientific Collecting Permits #011663 and #010579, Bureau of Land Management Ridgecrest Field Office Permit #1110 (CA-6601.26) P, and University of Georgia IACUC AUP #A2012 10-004-Y1-A0. Financial support provided by a University of Georgia Presidential Fellowship.

***UNGALIOPHIS PANAMENSIS* (Southern Bromeliad Boa)**. PANAMÁ: PANAMÁ OESTE: Altos del Maria (8.63333°N, 80.06666°W; WGS 84), 700 m elev. 24 June 2006. Julie M. Ray, Edgardo J. Griffith, and Heidi L. Ross. Verified by James L. Knight. Amphibian and Reptile Diversity Research Center, University of Texas at Arlington (UTADC 6977, photo voucher). First record for the former Panamá Province and the new Panamá Oeste Province (Köhler 2008. Reptiles of Central America, 2nd ed. Herpeton Verlag, Offenbach. 200 pp.). The snake was found on the ground in primary premontane cloud forest. I thank the TADS project for logistical support and E. J. Griffith and H. L. Ross for assistance in the field.

JULIE M. RAY, La MICA Biological Station, El Copé de La Pintada, Coclé Province, Republic of Panamá; e-mail: julie.ray@lamica.org.

***XENOCHROPHIS VITTATUS* (Striped Keelback)**. USA: PUERTO RICO: Municipality of Carolina: Carolina Pueblo Country Club, 409 Street (18.408226°N, 65.961828°W; WGS84), 3 m elev. 22 July 2013. Brian Ríos-Dróz. MZUPRRP-R-15001. 504 Street (18.418684°N, 65.962445°W; WGS84), 0 m elev. 22 July 2013. Brian Ríos-Dróz. MZUPRRP-R-15002. Both verified by R. Graham Reynolds. First records from the Western Hemisphere for this snake normally native to Indonesia. Several other sightings of reproductively mature adults and juveniles, from separate locations in the Municipality of Carolina made by AH-M and others since 2011, indicate a well-established population on Puerto Rico. Time of introduction is unknown, but anecdotal accounts of "garter snake" sightings in the region are traced back to about 1994 and were thought to be accidental escapees from shipping containers, presumably destined for the pet trade, at the Luis Muñoz Marín International Airport, located ca. 4.5 km NW from collection sites.

ERRATUM

The latitude coordinates reported by Maxwell and Scott (2014. Herpetol. Rev. 45:466) for a record of *Pituophis m. melanoleucus* in Carroll Co., Tennessee, USA, should read 35.9354ºN instead of 36.9354ºN. The coordinates as published place the record in Marshall Co., Kentucky, whereas the correct coordinates put the record at the "gate to Carroll County Recreation Lake" as stated in the report.

A. FLOYD SCOTT, Department of Biology and Center of Excellence for Field Biology, Austin Peay State University, Clarksville, Tennessee 37044, USA; e-mail: scotta@apsu.edu.

The island of Borneo is the largest of the Sundaic subregion (which comprises the Malay Peninsula, Sumatra, Java, Borneo, Bali, and smaller associated islands), and is the second largest tropical island in the world. Previously covered in mixed dipterocarp forest, it contains some of the last remaining continuous tracts of tropical rainforest in Southeast Asia and is recognized as one of the most biodiverse areas of the Indo-Malayan region (MacKinnon et al. 1996). However, Borneo experiences one of the highest deforestation rates in the world, with 1.7% of its forests converted annually primarily through commercial timber harvesting and conversion of forests to monoculture plantations (Koh 2007; Langer et al. 2007). While about 9% of the land area is afforded some level of protection, such protected areas are isolated and dwarfed by the vast areas designated for timber extraction and monoculture plantations (Brodie and Giordano 2011). The viability of such protected areas for the conservation of Borneo's biodiversity is thus questionable (Meijaard et al. 2005).

Borneo boasts high herpetofaunal species richness and endemism, with 290 reptiles and 164 amphibian species currently described, making it the richest in terms of herpetofaunal diversity of the greater Sundas (compared to Sumatra: 218 reptiles and 93 amphibians, Java: 173 reptiles and 36 amphibians and Sulawesi: 115 reptiles and 40 amphibians; Das and van Dijk 2013).

Most herpetofaunal studies in Borneo have focused on protected areas. Little work has been conducted in modified landscapes such as logging concessions and monoculture plantations. In the Malaysian state of Sarawak, only 4% of the total land area is protected, whereas 35% is designated for

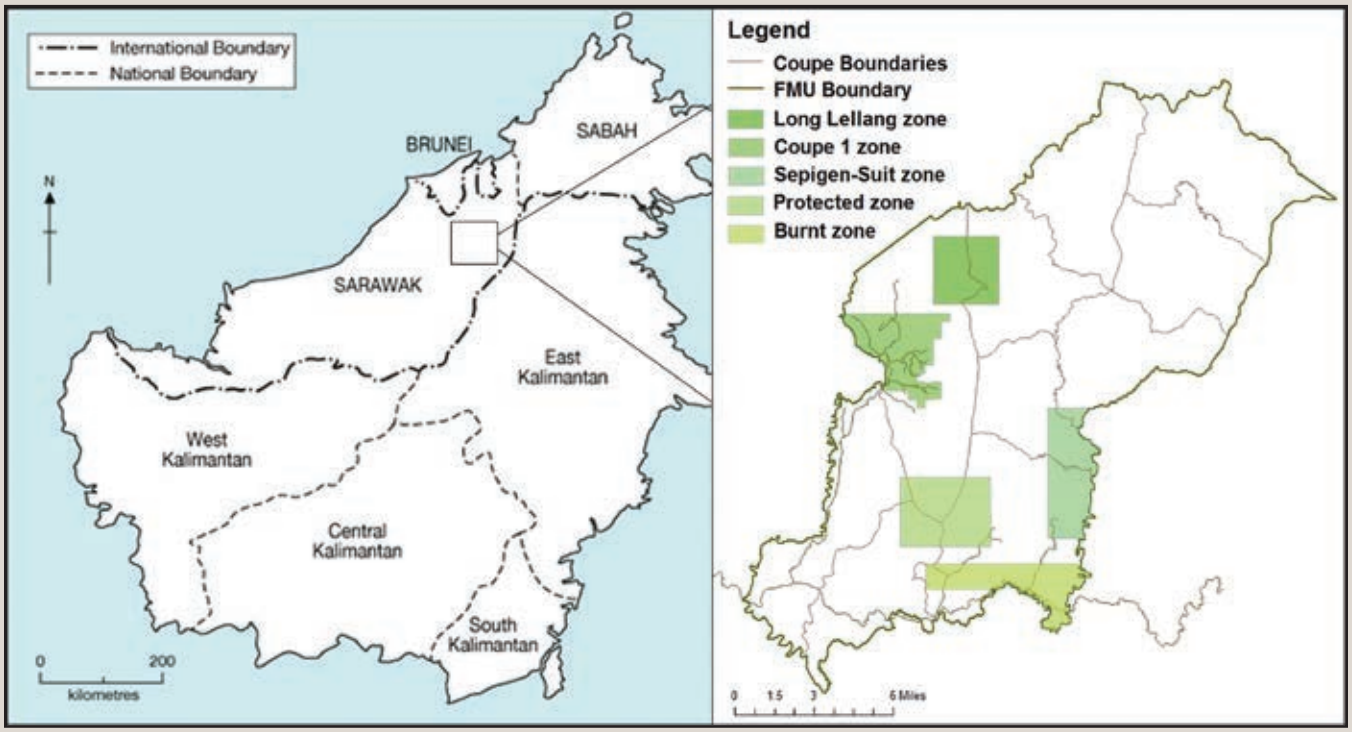

FIG. 1. Map of Borneo featuring the location of the Sela'an Linau Forest Management Unit (FMU) and location of our study sites therein. Study site habitat types, elevation range, and anthropogenic disturbance are as follows (modified from Mathai and Buckingham 2014). Long Lellang: Hill and submontane primary forest with some montane forest in higher elevation areas, 575–1200 m elev., low anthropogenic disturbance. Coupe 1: Secondary-growth lowland forest; the majority of the area was subject to reduced impact logging in 2006 and 2007; some unlogged lowland and hill forest, 500–900 m elev., moderate anthropogenic disturbance. Sepigen-Suit Zone: Lowland (mainly secondary) forest with active *temudas* and rice paddies, 250–475 m elev., high anthropogenic disturbance. Protected Zone: Primary submontane forest with some montane forest in the higher elevation areas, 750–1550 m elev., low anthropogenic disturbance. Burnt Zone: Secondary-growth lowland forest (the majority of the area was burned during the 1997–1998 El Niño event), 250–750 m elev., high anthropogenic disturbance.

logging activities (Sarawak Forest Department 1997). To better manage biodiversity in these modified landscapes, it is essential that assessment and monitoring of ecosystem dynamics and community structure be conducted. Thus providing more comprehensive data for conservation management (Meijaard et al. 2005).

The present study was conducted in the Sela'an Linau Forest Management Unit (FMU), a logging concession of 55,949 ha located in the Upper Baram region of northern Sarawak, Malaysian Borneo (Fig. 1). The licensed concessionaire is Samling. Roughly half the area was conventionally logged in the past and since 2003, a reduced impact logging (RIL) has been applied. The majority of the area supports mixed dipterocarp forest (60%), with some montane forest (4%), tropical heath forest (*kerangas*) (21%), and slash and burn areas (*temuda*) (15%). Roughly 3000 ha of forest was destroyed during the 1997–1998 El Niño event though secondary growth, regenerating forest has now reclaimed the area. Elevation ranges from 250–2000 m above sea level. The area receives high rainfall with 3400–5900 mm falling annually and temperatures averaging 26°C and 14°C in the low and high elevation areas, respectively (Mathai et al. 2010).

Methods.—The herpetofaunal records presented in this paper are opportunistic detections obtained during an ongoing small carnivore camera-trapping and habitat modelling study. Five field trips totalling 178 days were made between April 2013 and July 2014. During this time, opportunistic herpetofaunal surveys were conducted in five survey sites (Protected zone, Burnt zone, Sepigen-Suit zone, Coupe one zone, and Long Lellang zone) each of an area 10–15 km^2. These areas compromised a mix of undisturbed and disturbed lowland, hill, submontane and montane forest with elevations ranging between 220–1300 m elevation (see Fig. 1).

Observations were made during the day (0800–1700 h) while walking transects for habitat analysis and setting of camera-traps. Between three to seven kilometers were walked each day; however, it is acknowledged that as researchers were not specifically surveying for herpetofauna, many specimens may have been missed and microhabitats specific to herpetofauna (tree buttresses, beneath logs/rocks, and within tree cavities) were rarely searched.

When possible, night walks were conducted along streams and old logging roads, specifically targeting herpetofauna. Such walks were conducted mainly after rain and microhabitats specific to herpetofauna were searched.

All specimens detected were photographed. GPS coordinates of detection sites, date, time of encounter, and habitat type were recorded. Snout–vent length (SVL) and brief behavioral notes were taken wherever possible. All voucher specimen photographs have been registered with the Lee Kong Chian Natural History Museum, National University of Singapore.

Results and discussion.—Opportunistic sampling detected 36 reptile species (16 lizards, 18 snakes, and two turtles) comprising 12 families, including 12 species endemic to Borneo. A total

TABLE 1. Herpetofaunal species recorded from Sela'an Linau Forest Management Unit, Upper Baram, Sarawak, East Malaysia, between April 2013 and July 2014. of 18 amphibian species comprising six families, including 11 species endemic to Borneo, were also detected (see Table 1). This represents 12.41 and 11.92% of all known Bornean reptile and amphibian species, respectively (calculated from Das 2011; Haas et al. 2013). All reptiles encountered (with the exception of two montane species, *Phoxophrys spiniceps* and *Popeia sabahi*) were lowland forest-dwelling species.

Of the 36 reptile species recorded, 10 were detected on more than one occasion: three snake species, *Aplopeltura boa, Asthenodipsas laevis,* and *Parias sumatranus,* and seven lizard species, *Gonocephalus grandis, Cyrtodactylus consobrinus, C. malayanus, C. pubisulcus, Aeluroscalabotes felinus, Draco cornutus,* and *Dasia vittata*; the latter three are often associated with anthropogenically altered habitats (Das 2010). *Draco cornutus* and *Dasia vittata,* as well as *Naja sumatrana* and *Bronchocela cristatella,* were only encountered in a lowland village area.

Of the 18 amphibians detected, all were lowland forest dwellers with the exception of four exclusively montane species: *Ansonia longidigita, Philautus ingeri, Philautus macroscelis,* and *Philautus petersi.* Half of all species detected were exclusively riparian and/or dependent on riparian habitats for breeding (Inger et al. 1997).

A total of nine amphibian species were observed on more than one occasion with five of these observed with considerable frequency. *Philautus petersi, Feihyla kajau,* and *Leptobrachella parva* were commonly heard and sighted at night along riparian margins in the higher elevation areas (800–1200 m elev.), and *Staurois natator* and *Staurois latopalmatus* were commonly sighted by day among fast-flowing rivers in lower elevation areas (350–500 m elev.).

Two amphibians, *Pelophryne signata* and *Kalophrynus subterrestris* are considered lowland species, and have only previously been recorded below 1000 m and 300 m elevation, respectively (Inger et al. 1997). During this study *P. signata* was detected at 1200 m elevation, with *K. subterrestris* detected at 1100 m elevation, significantly increasing the known elevation ranges of these amphibians.

Due to the limited time frame and opportunistic nature of our observations, no inferences can be drawn regarding true herpetofaunal diversity and abundance in the region. As such, it is recommended that more surveys specifically targeting herpetofauna be conducted within this logging concession and other concessions and modified landscapes throughout Sarawak and Borneo. Understanding of herpetofaunal diversity and community dynamics within these large unprotected regions is crucial to identify areas of high conservation priority and identify possible management strategies that could alleviate further biodiversity loss, particularly in the face of Borneo's rapid deforestation, forest conversion, and proposed mega-dam projects.

Acknowledgments.—This study was made possible as part of the ongoing research work conducted by the Hose's Civet and Small

Carnivore Project, Borneo (HOSCAP Borneo). HOSCAP Borneo is funded by the Care-For-Nature Trust Fund (administered by HSBC Trustee (Singapore) Limited), Ocean Park Conservation Foundation, Hong Kong, Yaw Teck Seng Foundation, MASwings, Idea Wild, and San Francisco Zoo and is conducted under the auspices of the Institute of Biodiversity and Environmental Conservation (IBEC), Universiti Malaysia Sarawak (UNIMAS). We express our gratitude to the Penan field guides from Long Sepigen, Long Kerong, Long Kepang, and Long Main. Sincere thanks are also expressed to Indraneil Das and Seth Wong for assistance with the manuscript and specimen identification, and to the GIS unit of Samling for assistance in providing shapefiles and creation of maps. For identification verification and providing Zoological Reference Collection (ZRC) voucher specimen numbers, we thank Kelvin K. P. Lim of the Lee Kong Chian Natural History Museum, National University of Singapore.

NATURAL HISTORY NOTES

The Natural History Notes section is analogous to Geographic Distribution. Preferred notes should 1) focus on observations in the field, with little human intrusion; 2) represent more than the isolated documentation of developmental aberrations; and 3) possess a natural history perspective. Individual notes should, with few exceptions, concern only one species, and authors are requested to choose a keyword or short phrase that best describes the nature of their note (e.g., Reproduction, Morphology, Habitat, etc.). Use of figures to illustrate any data is encouraged, but should replace words rather than embellish them. The section's intent is to convey information rather than demonstrate prose. Articles submitted to this section will be reviewed and edited prior to acceptance.

Electronic submission of manuscripts is requested (as Microsoft Word or Rich Text format [rtf] files, as e-mail attachments). Figures can be submitted electronically as JPG, TIFF, or PDF files at a minimum resolution of 300 dpi. Please DO NOT send graphic files as imbedded figures within a text file. Additional information concerning preparation and submission of graphics files is available on the SSAR web site at: http://www.ssarherps.org/HRinfo.html. Manuscripts should be sent to the appropriate section editor: **Sean P. Graham** or **Crystal Kelehear Graham** (amphibians; grahasp@tigermail.auburn.edu); **James Harding** (turtles; hardingj@msu.edu); **Charles Linkem** (crocodilians, lizards, and *Sphenodon*; herprev.ltc.nhn@gmail.com); and **John D. Willson** or **David A. Steen** (snakes; hr.snake.nhn@gmail.com).

A reference template for preparing Natural History Notes may be downloaded at: http://ssarherps.org/wp-content/uploads/2014/07/NatHistNotes_FormattingGuidelines.pdf. Standard format for this section is as follows: **SCIENTIFIC NAME** in bold, capital letters; standard English name in parentheses with only first letter of each word capitalized (if available, for the United States and Canada as it appears in Crother [ed.] 2012. *Scientific and Standard English Names of Amphibians and Reptiles of North America North of Mexico, with Comments Regarding Confidence in Our Understanding, 7th ed.* Herpetol. Circ. 39:1–92, available from SSAR Publications Secretary, ssar@herplit.com; for Mexico as it appears in Liner and Casas-Andreu 2008. *Standard Spanish, English and Scientific Names of the Amphibians and Reptiles of Mexico.* Herpetol. Circ. 38:1–162); **KEY WORD(S)** referring to the content of the note in bold, capital letters; content reporting observations and data on the animal; place of deposition or intended deposition of specimen(s), and catalog number(s) if relevant. Then skip a line and close with author name(s) in bold, capital letters (give names and addresses in full—spell out state names—no abbreviations, e-mail address after each author name/address for those wishing to provide it—e-mail required for corresponding author). References may be briefly cited in text (refer to this issue or the online template for citation format and follow format precisely). One additional note about the names list (Crother 2012) developed and adopted by ASIH-HL-SSAR: the role of the list is to standardize English names and comment on the current scientific names. Scientific names are hypotheses (or at least represent them) and as such their usage should not be dictated by a list, society, or journal.

Recommended citation for notes appearing in this section is: Goldberg, S. R., and C. R. Mahrdt. 2012. *Bogertophis rosaliae*: reproduction. Herpetol. Rev. 43:655.

CAUDATA — SALAMANDERS

***ANDRIAS JAPONICUS* (Japanese Giant Salamander). DIET.** *Andrias japonicus* is well known as one of the largest extant amphibians. The species is a high-order predator in Japanese river ecosystems and preys on a variety of invertebrates and vertebrates including mammals (Tochimoto 2002. Hyogo Biol. 12:134–139; Okada et al. 2008. Herpetol. Conserv. Biol. 3:192–202). At 1500 h on 30 March 2014, a local person observed a giant salamander regurgitating an embryo of a Sika Deer (*Cervus nippon*) in a small irrigation canal (width = 60–110 cm, depth = 10–20 cm) that originates from the Sayo River, in Sayo Town, Hyogo Prefecture, Japan (35.04861°N, 134.37083°E, datum WGS84; elev. 135 m; Fig. 1). The giant salamander (total length = 830 mm) was found as it was starting to expel its meal. On the following day (1548 h on 31 March 2014), we visited the place and the giant salamander was found to have again swallowed the deer embryo. However, as soon as we began measuring it, it started to regurgitate (Fig. 2), which took ca. 10 sec. to complete. The giant salamander weighed 4650 g before regurgitating the embryo and 3550 g

FIG. 1. Irrigation canal, originating from the Sayo River, Hyogo Prefecture, Japan. Arrow shows where the Japanese Giant Salamander was found.

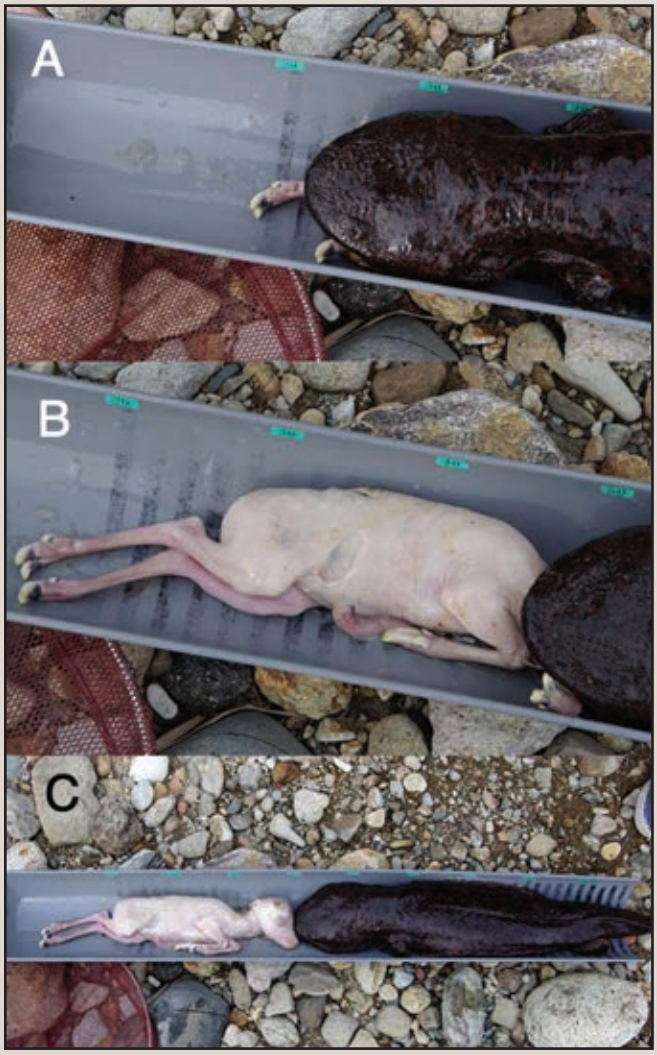

FIG. 2. An adult Japanese Giant Salamander (*Andrias japonicus*) regurgitating the embryo of a Sika Deer (A and B) and finally expelling it (C), on a handmade scale.

afterward. The embryo was 360 mm in length and weighed 1100 g. After measurements, we injected a PIT tag into the left shoulder of the giant salamander and released it to the main stream of the Sayo River (35.05750°N, 134.36694°E, datum WGS84; elev. 145 m). The embryo was probably discarded in the river by a hunter.

***CRYPTOBRANCHUS ALLEGANIENSIS ALLEGANIENSIS* (Eastern Hellbender). LARVAL/ADULT ASSOCIATION.** Hellbenders are generally considered solitary animals with a single animal primarily found under one rock throughout most seasons (Smith 1907. Biol. Bull. 13:5–30; Nickerson and Mays 1973. The Hellbenders. Milwaukee Public Museum, Milwaukee, Wisconsin. 106 pp.). However, during the breeding season more than one hellbender can be found under the same rock (Smith 1907, *op. cit.*; Bishop 1941. New York State Mus. Bull. 324:1–365; Peterson 1988. Herpetol. Rev. 19:28–29). Further, the fact that hellbenders are cannibalistic is well known (Nickerson and Mays 1973, *op. cit.*; Groves and Williams 2014. Herpetol. Rev. 45:108–109) and might explain the rare instance of more than one hellbender under the same rock when breeding season activities are not apparent. Most reported occurrences of hellbenders sharing a single rock outside the breeding season generally refer to adults of undetermined sizes and sexes (Smith 1907, *op. cit.*; Hillis and Bellis 1971. J. Herpetol. 5:121–126; Nickerson and Mays 1973, *op. cit.*). Because few intraspecific associations of hellbenders of differing age classes have been reported, the following observations are of interest. In each case the specific locality is withheld due to conservation concerns.

On 13 March 2004 in the Hiwassee River drainage, Union Co., Georgia, USA, we encountered an adult male *C. a. alleganiensis* (total length = 37.5 cm) under a rock (c. 0.5 x 0.5 m) with four conspecific larvae. The average total length of the larvae was 3.93 cm (range: 3.8–4.0 cm), and all larvae had noticeable yolk sacs, external gills, well-developed forelimbs, and small hind limbs. Based upon records of oviposition and nest guarding behavior occurring in September at this site (Jensen et al. 2004. Herpetol. Rev. 35:156), and given a 60–80 day incubation period (Hulse et al. 2001. Amphibians and Reptiles of Pennsylvania and the Northeast. Cornell University Press, New York. 419 pp.), it is possible these larvae hatched rather late in the season, within two–three weeks of this observation. However, little is known about embryonic development in the wild and what environmental factors affect development over winter.

On 29 June 2010 in the French Broad River drainage, Transylvania Co., North Carolina, USA, we collected an adult male *C a. alleganiensis* (total length = 42 cm) from under a large, flat rock measuring 1.2 x 1.2 m. Shortly after collecting the adult male, a small, gilled larval hellbender (total length = c. 5 cm) was observed walking and swimming from under the same rock. This rock was in run habitat with 0.5 m water depth and approximately 50–60 m from a large pool at the base of a small waterfall. The larva did not appear to be stressed or injured. After emerging from under the rock, the larva circled and walked back under it in the same area that the adult male returned to upon release. We were unable to capture this larva for processing before it re-entered the large rock.

In a final example, on 08 August 2012 in the Hiwassee River drainage, Cherokee Co., North Carolina, USA, we collected an adult male *C. a. alleganiensis* (total length = 37 cm) from under a large, flat rock measuring 1.2 x 2.1 m in size. During the capture, a gilled larva (total length = 7 cm) was swept into a net positioned on the downstream side of the rock. We noticed no injuries on the larva during processing. The rock was in run habitat with 0.3 m water depth and in a river section with bedrock and sand as the predominant substrate. After processing, both the adult male and the gilled larva were placed at the downstream entrance to the capture rock, where they both crawled back under and remained.

Although we cannot determine how long the larvae from each observation occupied the same rocks as the adult males, it is possible that the larvae were remaining young from the previous season's brood and were still being protected under their natal rocks by the adult males. The size of the larvae suggests that they

were less than one year of age (Bishop 1941, *op. cit.;* Nickerson and Mays 1973, *op. cit.*), which supports this hypothesis. Another possibility is that shelter rocks had separate cavities or compartments within that provided the larvae refuge from being in direct contact with the adults and were thus able to avoid being cannibalized. A third alternative that must be considered is that the larvae observed in the latter two observations may have entered the rocks of the adult males opportunistically immediately prior to our surveys. The hellbender populations at our three localities are robust and appear to be stable which could increase the chance of larval/adult associations.

We thank Shem Unger for encouraging us to report these observations.

GRAHAM**, Sul Ross State University, Department of Biology, Geology, and Physical Sciences, Alpine, Texas 79832, USA (e-mail: sean.graham@sulross.edu).

***PLETHODON CINEREUS* (Eastern Red-backed Salamander). MOVEMENT.** Lungless salamanders (family Plethodontidae) are relatively sedentary and are presumed to have limited dispersal ability (Marsh et al. 2004. Ecology 85:3396–3405). Site fidelity in Plethodontidae is high, and individuals displaced 90 m return to home territories (Kleeberger and Werner 1982. Copeia 1982:409–415). Individuals defend territories (Jaeger et al. 1982. Anim. Behav. 30:490–496) and female home ranges have been estimated to be 24.34 m^2 (Kleeberger and Werner 1982, *op. cit.*). Females may seek out suitable subsurface habitat to oviposit eggs, yet little is known about their maximum movement distances (Petranka 1998. Salamanders of the United States and Canada. Smithsonian Institution Press, Washington. 587 pp.).

On 18 September 2014, a female *P. cinereus* (lead back morphotype; SVL = 44.68 mm; 0.89 g) was found under a coverboard during a standard sampling event and uniquely marked using visual implant elastomer at the S.O. Conte Anadromous Fish Research Center, Massachusetts, USA (42.59280°N, 72.58070°W, datum WGS84; elev. 74 m). This individual was subsequently recaptured at ~1500 h on 8 October 2014 under a coverboard within 3 m of the original capture location and then again ~1430 h on 16 October 2014 under a log, within the same forest patch, though in a 50 x 150 m area adjacent to the original study area. Because we found the marked salamander while collecting multiple individuals for a laboratory study, the exact recapture location of the marked individual is not known. However, the distance between the 8 October capture location and the nearest edge of the 16 October search area (i.e. 50 x 150 m) was 143 m, indicating a minimum movement distance. As far as we are aware, this is the longest recorded movement for *P. cinereus* by more than 53 m (Kleeberger and Werner 1982, *op. cit.*). This finding followed a rain event of 1.63 cm within 24 h and the second largest sustained rain event during October. The movement we observed may have been due to disturbance from handling and marking, although this was minimized in the field.

SEAN C. STERRETT (e-mail: seansterrett@gmail.com), **ADRIANNE B. BRAND, WILLIAM R. FIELDS, RACHEL A. KATZ, EVAN H. CAMPBELL GRANT,** United States Geological Survey, Northeast Amphibian Research and Monitoring Initiative, Patuxent Wildlife Research Center, SO Conte Anadromous Fish Research Laboratory, One Migratory Way, Turners Falls, Massachusetts 01376, USA.

***PLETHODON HUBRICHTI* (Peaks of Otter Salamander). BEHAVIOR.** On 13 September 2014, while examining a site located near Onion Mountain, Bedford Co., Virginia, USA, where *Plethodon hubrichti* and *P. cinereus* are sympatric, we discovered a *P. hubrichti* (SVL ca. 48 mm) biting a *P. cinereus* (SVL ca. 30 mm) beneath a rock on the forest floor (Fig. 1). The *P. cinereus* visibly struggled during our observation with no noticeable effect on the *P. hubrichti*. The *P. hubrichti* appeared to have complete physical dominance over the *P. cinereus*. After a couple of minutes of observation, the *P. hubrichti* released its grasp and both salamanders retreated to the leaf litter. Both salamanders appeared to be unharmed.

Interference competition with *P. cinereus*, including agonistic behavior and territoriality, is thought to be a factor influencing the range boundaries of several Plethodontid species, including *P. hubrichti* (Arif et al. 2007. Evol. Ecol. Res. 9:843–854). The range of *P. hubrichti* is limited to a 19-km length of the Blue Ridge Mountains in Virginia and it is sympatric with the wide-ranging *P. cinereus* along the edge of its range (Petranka 1998. Salamanders of the United States and Canada. Smithsonian Institution Press, Washington, DC. 587 pp.). Aggressive behaviors, such as lunging and biting, have been documented between *P. hubrichti* and *P. cinereus*; however, most behavior studies take place in the laboratory and these behaviors are rarely observed in the field. Although there is no dietary evidence that suggests *P. hubrichti* regularly consumes other salamanders (Arif et al. 2007, *op. cit.*) the size difference between the observed individuals suggests that the *P. hubrichti* was capable of swallowing the *P. cinereus*.

FIG. 1. *Plethodon hubrichti* biting a smaller *P. cinereus*.

ANDREW KNIOWSKI, Department of Fish and Wildlife Conservation, Virginia Tech, Blacksburg, Virginia 24061, USA (e-mail: kniowski@vt.edu); **RENÉE PIETSCH,** Department of Biological Sciences, Virginia Tech, Blacksburg, Virginia 24061, USA.

***TRITURUS MACEDONICUS* (Macedonian Crested Newt). TAIL AUTOTOMY.** Tail autotomy is one of many anti-predator adaptations and is particularly common in lizards (e.g., Arnold 1988. *In* Gans and Huey [eds.], Biology of the Reptilia, Vol. 16, pp. 253–273 Alan R. Liss, New York; Bateman and Fleming 2009. J. Zool. 277:1–14). The tail plays an important role in defensive behavior in salamanders: it may be elevated, undulated, and wagged or convoluted, and autotomized (Brodie 1977. Copeia 1977:523–535; Jablonski and Balej 2014. Herpetol. Rev. 45:302–303). However, tail loss can result in loss of fitness as many animals, including

salamanders, use the tail to store energy as fat (Arnold 1988, *op. cit.*; Maginnis 2006. Behav. Ecol. 17:857–872; Bateman and Fleming 2009, *op. cit.*). Regeneration of the tail may require an increase in feeding rate and diversion of energy from growth or other life processes (Maginnis 2006, *op. cit.*; Marvin 2013. J. Herpetol. 47:174–178). Tail loss may also affect behavior, reproduction, and movement (e.g., swimming, running, and diving; Fox and McCoy 2000. Oecologia 122:327–334; Maginnis 2006, *op. cit.*; Marvin 2010. Copeia 2010:468–474; Marvin 2013, *op. cit.*). Cases of caudal autotomy in caudate amphibians are not usual; it is well established in salamanders of the family Plethodontidae, which occasionally can shed the end of their tails (e.g., Brodie 1977, *op. cit.*; Ducey et al. 1993. Biotropica 25:244–349; Romano et al. 2010. Acta Herpetol. 5:199–205).

Triturus macedonicus is an endemic and widespread species in western parts of the Balkans (Wielstra et al. 2014. Amphibia-Reptilia 35:376–381). On 4 October 2013, during fieldwork carried out in Albania, we discovered a population (approx. 20 individuals) of this species inhabiting a mountain waterhole in the Korab Mountains (41.6823°N, 20.5210°E, datum WGS84; elev. 1776 m). Several specimens were caught for photography and other documentation. Tail loss was recorded in one adult male during handling. The newt, after twisting movements of the tail, lost approximately 30 mm of the distal portion of its tail, accompanied with a small volume of blood. The discarded part of the tail then undulated approximately for 120 seconds. In other specimens of the same population regenerated tails were not observed. Several specimens (including the adult male) had old injuries on their tails. This observation was photographed and filmed (video available at: http://www.balcanica.info/video/Triturus_macedonicus_Albania_autotomy_131004.avi).

To our knowledge, this is the first observation of voluntary tail loss in the genus *Triturus*. However, we suggest that future research on skeletal morphology in crested newts is necessary.

ANURA — FROGS

***AMEEREGA TRIVITTATA* (Three-striped Poison-dart Frog). MALE SIZE AND REPRODUCTIVE SUCCESS.** Male *Ameerega trivittata* exhibit parental care by transporting tadpoles on their dorsum (Fig. 1) from their initial oviposition sites under leaves or palm sheaths to larger sources of standing water where they complete their development (Roithmair 1994. Copeia 1994:107–115). Males generally transport the entire brood in a single trip when tadpoles reach approximately 18 days of age (Roithmair 1994, *op. cit.*). Male body size has been used as a measure of mate quality in anurans. For example, larger males may be able to mate with larger and more fecund females (Bowcock et al. 2013. Current Zool. 59:747–753) or transport more tadpoles (Ringler et al. 2013. Front. Zool. 10:67). In dendrobatid species, where males transport their young, one measure of reproductive success is the number of tadpoles a male carries. Here we test the hypothesis that the number of tadpoles transported is positively correlated with male size.

This study was conducted 28 May 2013–03 June 2013 in Brownsberg Nature Park in the Republic of Suriname (4.94799°N, 55.18271°W; datum WGS 84). Twenty-three male *A. trivittata* carrying tadpoles were captured by hand or handheld net as they approached tadpole deposition sites. Deposition sites were water-filled puddles ranging from 3–15 m in the middle of a dirt road surrounded by forest vegetation. We measured SUL of each male to the nearest 0.01 mm using calipers, counted the number of tadpoles present using a 10x magnifying lens, and then released the male with his tadpoles at their point of capture. To statistically assess the relationship between the number of tadpoles transported and male SUL, we used Pearson product movement correlation (Minitab 16 statistical software, Minitab Inc., State College, Pennsylvania). Male SUL ranged from 33.1 to 38.9 mm (mean = 35.7 mm, SD = 1.61). The number of tadpoles transported ranged from 3–28 (mean = 17.6, SD = 7.15). We found a significant positive correlation between the number of tadpoles transported and male SUL ($N = 23$; $p < 0.003$; $r = 0.60$; Fig. 2). In contrast, the number of tadpoles transported was not correlated with male size in male *A. trivittata* in Peru (Roithmair 1994, *op. cit.*). This lack of relationship may simply be due to limited

FIG. 1. Male *Ameerega trivittata* transporting tadpoles to a large puddle in Brownsberg Nature Park, Republic of Suriname.

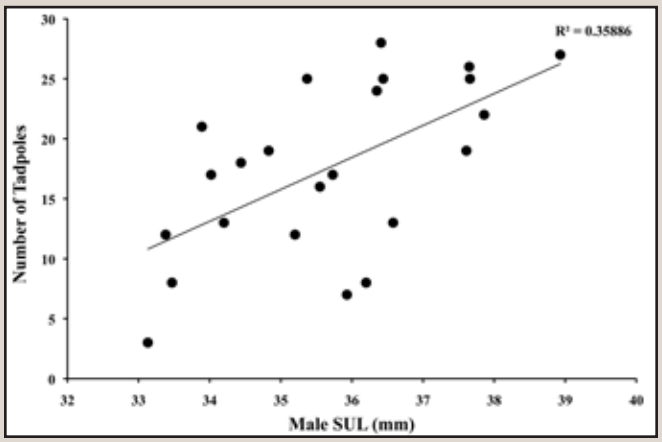

FIG. 2. Correlation between the number of tadpoles transported and male snout–urostlyle length in *Ameerega trivittata* at Brownsberg Nature Park, Republic of Suriname.

sample size (N = 8 versus N = 23 in the current study) or it may represent population differences in female choice, paternal care, clutch size, or predation of eggs or tadpoles before transport. Further research may elucidate whether factors involving female choice or paternal care result in the positive relationship between tadpole numbers and male size.

We thank Paul Ouboter for his help and suggestion of a field site, Robby Dragman for his assistance in coordinating field and lodging logistics, and Tom Mathies and Paul Kaseloo for providing valuable suggestions on the manuscript. Funding was provided by a National Science Foundation HBCU-UP (USA) grant to C. d'Orgeix.

***ANAXYRUS WOODHOUSII* (Woodhouse's Toad). NECROPHILIA.** Necrophilia has been reported previously for amphibians (e.g., Meshaka 1996. Florida Sci. 59:74–75; Bettaso et al. 2008. Herpetol. Rev. 39:462; Sinovas 2009. Herpetol. Rev. 40:199; Overvides and Zaidan 2013. Herpetol. Rev. 44:655–656), but these reports documented only the discovery of amplexed pair(s). Herein I report persistence of a male *Anaxyrus woodhousii* amplexing a deceased anuran.

At 1525 h on 10 May 2014 one of us (JCJ) observed a male *A. woodhousii* in axillary amplexus with a dead, bloated toad (Fig. 1) at an abandoned slate mine pool at the Ouachita Mountains Biological Station, Arizona, USA (34.45811°N, 93.99894°W, datum WGS84; elev. 488 m). At 1330 h the following day (11 May 2014) the pair was under a partially submerged stem at the southwest corner of pool, approximately 2.5 m from the original location. The male *A. woodhousii* moved its left hind leg, apparently to maintain an upright position as the carcass seemed to be tilting; the wind created a small clockwise current in the pool. At 1400 h the following day (12 May 2014), the pair was still in the southwest corner of the pool; the male toad was still moving its legs. JCJ was unable to locate the pair on 13 May 2014; there had been 56 mm rain overnight. On 14 May 2014, JCJ discovered the intact, upside down, carcass of the female toad; LMH confirmed the amplexed individual as a female *A. woodhousii.*

Bull (2000. Behav. Process. 51:7–20) reported that a male *Tiliqua rugosa* (Sleepy Lizard) courted a dead female conspecific for two days. The toads reported here were in amplexus for at least 45 h. It is unclear when the toads initially amplexed; the first rain of the month (73.66 mm), which filled the pool, was on 9 May 2014.

FIG. 1. *Anaxyrus woodhousii* amplexing a deceased partner on 10 May 2014.

JO-ANN C. JENNIER, Ouachita Mountains Biological Station, 281 Polk Road 615, Mena, Arizona 71953, USA (e-mail: jjennier@msn.com); **LAURENCE M. HARDY**, Museum of Life Sciences, Louisiana State University at Shreveport, 1 University Place, Shreveport, Louisiana 71118, USA.

***CROSSODACTYLUS GAUDICHAUDII.* PREDATION.** Anuran larvae are an important component of the food web in aquatic ecosystems. Most tadpoles feed on algae, detritus and/or other animals (Altig et al. 2007. Freshwater Biol. 52:386–395), and incorporated nutrients are transferred to the next trophic level when they are consumed by fish and macro-invertebrate predators. Crabs are one of the most important invertebrate predators of anurans, preying on both adults and larvae (Wells 2007. The Ecology and Behavior of Amphibians. University of Chicago Press, Chicago, Illinois. 1400 pp.; Pyke et al. 2013. Herpetol. Notes 6:195–199). However, there is a lack of information about predation on tadpoles by macro-detritivores in Atlantic Forest streams. Here, we report a common freshwater crab species from the Atlantic rainforest feeding on a tadpole in a permanent water body habitat.

At 2230 h on 22 January 2014, during visual encounter surveys near the Cachoeira das Almas waterfall (22.948855°S, 43.286212°W, datum WGS84; elev. 561 m), in Tijuca National Park (a remnant of the Atlantic Forest Biome), Rio de Janeiro, Brazil, we found a *Trichodactylus petropolitanus* (Freshwater Crab) feeding on a tadpole of *Crossodactylus gaudichaudii* (Fig. 1). They were found upon a rock in the stream, close to the water. The tadpole was already partially eaten, so we are unable to describe the predation event, or determine whether the tadpole was alive at the time of predation. However, considering the fresh appearance of its flesh it did not appear to be in decomposition. The *T. petropolitanus* hid itself due to our presence, and did not release the tadpole. Crabs have been reported preying on *Crossodactylus schmidti* (Caldart et al. 2011. North-West J. Zool. 7:342–345). With this finding, we add an additional example of

FIG. 1. *Trichodactylus petropolitanus* feeding on a tadpole of *Crossodactylus gaudichaudii.*

the link in the complex trophic chain in Atlantic Forest streams, where tadpoles are a food resource for freshwater crabs.

TATIANA MOTTA-TAVARES (e-mail: tmottatavares@gmail.com), **PAULO NOGUEIRA-COSTA**, **ARICIA DE OLIVEIRA MACHADO**, Programa de Pós-Graduação em Ecologia e Evolução, Universidade do Estado do Rio de Janeiro, Pavilhão Haroldo Lisboa da Cunha, Sala 220, Rua São Francisco Xavier, 524, Maracanã, 20550-013, Rio de Janeiro, Rio de Janeiro State, Brazil; **JORGE ANTÔNIO LOURENÇO PONTES**, Programa de Pós-Graduação em Ensino, Ambiente e Sociedade, Departamento de Ciências, Universidade do Estado do Rio de Janeiro, Rua Dr. Francisco Portela, 1470, Patronato, 24435-005, Rio de Janeiro, Rio de Janeiro State, Brazil; and **CARLOS FREDERICO DUARTE ROCHA**, Programa de Pós-Graduação em Ecologia e Evolução, Universidade do Estado do Rio de Janeiro, Pavilhão Haroldo Lisboa da Cunha, Sala 224, Rua São Francisco Xavier, 524, Maracanã, 20550-013, Rio de Janeiro, Rio de Janeiro State, Brazil.

***DENDROBATES AURATUS* (Green and Black Dart-poison Frog). TADPOLE DEPOSITION SITE.** Artificial structures can provide valuable rearing habitat for amphibians. Many frogs use both natural and artificial structures for breeding and parental care. However, little information exists regarding the use and characteristics of larger artificial structures for dendrobatids. *Dendrobates auratus* is widely distributed across Panama (Dunn 1941. Copeia 1941:88–93). Males of this species practice parental care by tending and actively transporting larvae in response to changing water conditions or rainfall (Wells 1978. Herpetologica 34:148–155). Here I report on the use of an artificial structure for tadpole deposition by *D. auratus*.

On 21 August 2014, I observed an adult male *D. auratus* (SVL = ca. 32 mm) with two larvae (Gosner stage 26–30) on its back (Fig. 1A). The adult frog was moving and depositing larvae in an artificial concrete structure (Fig. 1B) at a private residence surrounded by secondary forest and small forest patches in Chiriquí province, Panama (8.202724°N, 82.196791°W, datum WGS84; elev. 31 m). The structure measured 36.8 cm by 8.2 m and was filled with leaf litter with a water depth of 7.1 cm from recent rainfall. I observed seven *D. auratus* tadpoles within the artificial structure. This observation of frogs using larger than usual deposition sites provides information for future management of dendrobatid frogs as an alternative to previously described smaller artificial phytotelmata and tadpole rearing cups attached to tree trunks, which have proven successful as artificial breeding sites (Brown et al. 2009. Anim. Behav. 77:547–554; Stynoski 2009. Anim. Behav. 78:1351–1356).

Thanks to Nicholas L. Unger for helping record data.

***LEPTODACTYLUS VASTUS* (Northeastern Pepper Frog). CANNIBALISM.** *Leptodactylus vastus* (recently separated from *Leptodactylus labyrinthicus*) occurs in northeastern Brazil, primarily in Caatinga and adjacent Cerrado habitat (Heyer 2005. Arq. Zool. 37:269–348). Conspecific predation events are reported for a few anuran species, usually among large species (Toledo et al 2007. J. Zool. 271:170–177). Here we report a cannibalism event of *L. vastus*. At 0900 h on 25 May 2014 at Reserva Sapiranga, municipality of Mata de São João, state of Bahia, Brazil (12.570645°S, 38.045959°W, datum WGS84; elev. 18 m) we observed a large adult *L. vastus* in the leaf litter near a pond at the edge of a river (Rio Pojuca). It had the partially ingested left leg of a younger *L. vastus* in its mouth (Fig. 1). The prey was alive but already had most of its thigh eaten. The predator remained still until we tried to capture it; it then fled into the river holding its

FIG. 1. Adult *Leptodactylus vastus* holding and injuring the left leg of a younger conspecific.

prey in its mouth. *Leptodactylus vastus* has preyed on other vertebrates such as bats (Gouveia et al. 2009. Herpetol. Rev. 40:210) and snakes (Ferreira et al. 2012. Herpetol. Rev. 43:147); however, this is the first report of adult cannibalism in this species. Cannibalism has been observed in tadpoles of *L. labyrinthicus* (Silva et al. 2005. J. Nat. Hist. 39: 555–556); under current taxonomy that observation may now be assigned to *L. vastus*.

This observation occurred during a field survey under ICMBio/SISBIO permit Nº 23355-2.

FRANCISCO PÉRICLES BRANCO BAHIENSE GUIMARÃES, Universidade Católica do Salvador, Centro de Ecologia e Conservação Animal – ECOA, Avenida Prof. Pinto de Aguiar, 2589, CEP 41740-090, Pituaçu, Salvador, BA, Brazil (e-mail: bahiense.f.p.b.g@gmail.com); **RICARDO MARQUES**, Universidade Estadual de Santa Cruz – UESC, Campus Soane Nazaré de Andrade, km 16 Rodovia Ilhéus-Itabuna, Ilhéus, Bahia, Brazil (e-mail: rcdmarquess@gmail.com); **MOACIR SANTOS TINÔCO**, Programa de Pós-Graduação - Planejamento Ambiental– ECOA-UCSAL; The University of Kent, Canterbury – DICE, Marlowe Building, Kent, CT2 7NZ (e-mail: moacirtinoco@gmail.com).

***LEPTODACTYLUS VASTUS* (Northeastern Pepper Frog). DIET.** *Leptodactylus vastus* is a large terrestrial, nocturnal leptodactylid found in northeastern Brazil (Roberto et al. 2012. Biota Neotrop. 13:320–330); it belongs to the *pentadactylus* group and was recently split from *L. labyrinthicus* (Heyer 2005. Arq. Zool. 37:269–348). In the current work, we present occurrence of predation of *Physalaemus albifrons* (Bahia Dwarf Frog) by *L. vastus*. Five specimens of *L. vastus* (all males; mean SVL = 10.8 ± SD 1.3 cm; range = 9.1–12.6 cm) were collected in the municipality Aiuaba at the Ecological Station of Aiuaba, Brazil (6.573476°S, 40.123564°W, datum SAD69; elev. 466 m) on 27 March 2011 and examined. A total of seven specimens of *P. albifrons* (mean SVL = 2.3 ± SD 0.5 cm; range = 2.1–3.4 cm) were recovered: two in the stomach of one *L. vastus* and five in another. Voucher specimens were deposited in the herpetological collection of the Universidade Regional do Cariri–URCA-H (LZ 1309 and LZ 1320 for *L. vastus* and *P. albifrons*, respectively). *Physalaemus albifrons* is a small anuran, found in northeastern Brazil (Roberto et al. 2012. Biota Neotrop. 13:320–330). To our knowledge, this is the first time *P. albifrons* has been documented in the diet of *L. vastus*.

We thank Igor Roberto Joventino for identifying the *Physalaemus albifrons* and CAPES for the scholarship granted to DAT, AAMT, and SCR. FUNCAP provided a scholarship to JKR and CNPq provided a schorlaship to SCR. ICMBio granted permission to collect under license SISBIO (System Authorization and Information on Biodiversity, No. 27542-2, process no. 96683918).

***ODONTOPHRYNUS MAISUMA*. ATTEMPTED PREDATION.** *Odontophrynus maisuma* is a recently described fossorial frog restricted to coastal areas of Uruguay and southern Brazil (Rosset 2008. J. Herpetol. 42:134–144). Some information has been published on its ecology, but data on its predators are lacking. During a herpetological survey of a grassland area associated with coastal sand dunes in the municipality of Rio Grande, Rio Grande do Sul, Brazil (32.2175°S, 52.2222°W, datum WGS84; elev. 3 m), we observed a xenodontine snake *Lygophis anomalus* attempting predation on *O. maisuma*. At 1120 h on 17 September 2014, we observed an adult female *L. anomalus* (total length = 55 cm) in grassland with its head burrowed in the ground. The snake was attempting to pull the frog from its burrow, and loops of the snake's body were braced against the grass for leverage. During photography of the event, we disturbed the snake, which immediately released the frog and began to tongue flick rapidly. The frog had inflated its body and was injured on the right portion of its head (Fig. 1). After 10 min. the snake fled, leaving the frog at the burrow entrance. The frog remained inflated for around one minute then retreated to its burrow.

Fig. 1. Adult *Odontophrynus maisuma* and *Lygophis anomalus* following predation attempt.

Lygophis anomalus feeds on a variety of vertebrates, primarily anurans (Panzera and Maneyro 2014. South Am. J. Herpetol. 9:75–82). Panzera and Maneyro (2014, *op. cit.*) found representatives of six anuran families as prey; however, this is the first report of *O. maisuma*. Both *L. anomalus* and *O. maisuma* inhabit wet environments and open grasslands and their distribution overlaps in coastal zones of Uruguay and southern Brazil. Thus, we suggest that predation of *O. maisuma* by *L. anomalus* may be a frequent occurrence in these areas.

LEONARDO FELIPE BAIROS MOREIRA (e-mail: leonardobm@gmail.com), and **NATÁLIA PALUDO SMANIOTTO**, Universidade do Vale do Rio dos Sinos, Av. Unisinos, 950, São Leopoldo, Rio Grande do Sul, Brazil.

***OSTEOPILUS SEPTENTRIONALIS* (Cuban Treefrog). CANNIBALISM.** *Osteopilus septentrionalis* is an invasive exotic anuran in southwest Florida. The rate at which *O. septentrionalis* has spread across the South Florida landscape and the possible impacts it is having to native treefrogs has been studied with little hope given to any potential control. It has been suggested that one of the major characteristics allowing their spread is a generalized adult diet and the propensity of their tadpoles to employ cannibalism (Babbitt et al. 2000. Copeia 2000:469–474). At 0900 h on 11 October 2014, we witnessed an adult *O. septentrionalis* cannibalizing a juvenile (Fig. 1) in the vegetation near the parking lot of the CREW Marsh Hiking Trails, Collier Co., Florida, USA (26.492096°N, 81.534240°W; datum WGS84). Post-metamorphic cannibalism in this species is often written about in non-scientific literature and species accounts with no evidence presented to substantiate the claims (Johnson 2013. The Cuban

FIG. 1. Adult *Osteopilus septentrionalis* cannibalizing a juvenile.

Treefrog (*Osteopilus septentrionalis*) in Florida. http://edis.ifas.ufl.edu/pdffiles/UW/UW25900.pdf; 8 December 2014). In fact, most use the word "cannibalism" to mean that they eat other frogs rather than conspecifics (http://allaboutfrogs.org/info/species/cuban.html; 8 December 2014). We fully expect that others have observed similar behaviors as our own in this species. And in fact, it has been demonstrated in lab experiments (Wyatt and Forys 2004. Southeast. Nat. 3:695–700). However, definitive proof of post-metamorphic cannibalism has not been scientifically documented in wild populations of *O. septentrionalis*, which is the purpose of this note. Future research should be done to determine if this was an isolated event, a common opportunistic event with little impact at the population level, or if it is a density-dependent prey-switching behavior that represents a new self-regulation system within this invasive population.

JOHN E. HERMAN (e-mail: jherman@fgcu.edu), **ALEXANDRA BENTON**, and **IVETTE NIKOL IRIZARRY**, Department of Biological Sciences, Florida Gulf Coast University, 10501 FGCU Boulevard South, Fort Myers, Florida 33965, USA.

***PELOBATES FUSCUS* (Common Spadefoot). REPRODUCTIVE BEHAVIOR.** Calling in immature amphibian specimens has been observed in several European anurans, including *Pelobates fuscus*. Calling in *P. fuscus* has been observed in pre-adults (SVL = 33–37 mm; Müller 1984. Salamandra 20:121–142). Males generally reach sexual maturity at the age of two and females at the age of three years (Wiener 1997. *In* Hödl et al. [eds.], Populationsbiologie von Amphibien: Eine Langzeitstudie auf der Wiener Donauinsel, pp. 165–181. Stapfia 51). As they mature, male *P. fuscus* develop oval glands on the dorsal surface of the front legs which can appear nine months after metamorphosis (SVL = 37.3–40.4 mm; mass = 5–10 g; Nöllert 1990. Die Knoblauchkröte. A. Ziemsen Verlag, Wittenberg Lutherstadt. 144 pp.). What is notable in *P. fuscus* is that the females also emit vocalizations (Seglie et al. 2013. Bull. Soc. Herpetol. Fr. 145–146:61–72). Here we describe calling activity and the forming of a lumbar amplexus in captive post-metamorphic *P. fuscus*.

On 20 April 2012 small portions (8–10 cm) of eleven *P. fuscus* egg strings were collected from Valthe population in Drenthe province, the Netherlands (52.505747°N, 6.525512°E; datum WGS84) and the subsequent larvae were reared as part of a reintroduction program. The majority of larvae were released into the wild prior to metamorphosis. Some specimens were retained for educational purposes. Metamorphosis occurred at approximately eleven weeks of age after which they were kept terrestrially in groups of up to five animals in small terraria (30 x 38 x 25 cm) with a sandy soil substrate taken from their natural habitat. Invertebrates such as *Acheta domesticus, Alphitobius laevigatus*, and *Lumbricus terrestris* were offered twice a week and water was permanently available in a small bowl. After being kept in these terraria for two weeks, two individuals (SVL = 28 and 30 mm; mass = 3.0 g and 3.2 g) were placed in shallow water (approx. 4 cm deep) from 21–29 July 2012. Oval glands were absent in these specimens so sex determination was impossible. From 24 July 2012 on, calling activity was observed sporadically on a daily basis. During the only three visual observations, calling took place at the water surface; it is unknown if it also occurred in a submerged position, a behavior that *P. fuscus* normally exhibits. Calling was always brief and only observed during the day, mainly between 1000 h and 1700 h. The sound differed from that of adults in duration and pitch but was not recorded and it proved impossible to discern whether both specimens exhibited this behavior. On 27 July 2012, at 1500 h, two longer lasting calling periods were observed. A visual checkup showed the juveniles had formed a lumbar amplexus which lasted approximately 28 minutes. Our case further demonstrates that calling and the formation of lumbar amplexus can be observed in post-metamorphic *P. fuscus* only two weeks post-metamorphosis; thus prior to their first hibernation.

We thank A. Nöllert for reviewing a draft of this correspondence.

RICHARD P. J. H. STRUIJK (e-mail: r.struijk@ravon.nl), **WILBERT BOSMAN**, Reptile, Amphibian & Fish Conservation Netherlands, Natuurplaza, Toernooiveld 1, 6525 ED Nijmegen, the Netherlands; **WARREN SPENCER**, Artis Royal Zoo, Plantage Kerklaan 38-40, 1000 HD Amsterdam, the Netherlands.

***PELOBATES SYRIACUS* (Syrian Spadefoot). CANNIBALISM.** Cannibalism has been observed in early life history stages of many amphibian species (Babbitt and Meshaka 2000. Copeia 2000:469–474; Pfennig and Murphy 2000. Evolution 54:1738–1749; Vera Candioti 2005. Acta Zool. 86:1–11); however, less is known about cannibalism in the terrestrial phase of the anuran life cycle. Herein we report cannibalism in a *Pelobates syriacus* . On 12 July 2013 we witnessed an adult male *P. syriacus* (SVL =

FIG. 1. Adult male *Pelobates syriacus* attempting to ingest a conspecific juvenile.

66.2 mm, 35.9 g) trying to swallow a juvenile of the same species (SVL = 37.4 mm, 7.0 g; Fig. 1); while we were taking pictures the adult regurgitated its prey, which seemed to be unharmed, and we were able to measure them both. The observation was made in the southern part of the Danube Delta Biosphere Reserve (Constana Co., Romania), on a natural levee (Grindul Lupilor) separating Lakes Zmeica and Sinoe (44.620194°N, 28.812306°E, WGS84; elev. -2 m). After the mass land migration of newly metamorphosed spadefoots on 18–20 June 2013, a high density of juveniles was recorded at the site (up to 8800 juveniles/ha, unpubl. data). As far as we are aware, our observation is the first record of cannibalism for this species.

This observation is part of our study on *Pelobates* species supported by the Romanian National Authority for Scientific Research, CNCS-UEFISCDI grant, project number PN-II-ID-PCE-2011-3-0173.

TESTUDINES — TURTLES

***CHELYDRA SERPENTINA* (Snapping Turtle). WATERFOWL PREDATION.** *Chelydra serpentina* is an omnivorous resource generalist that has been observed preying on aquatic and semi-aquatic birds (Ernst and Lovich 2009. Turtles of the United States and Canada, 2nd ed. Johns Hopkins Univ. Press, Baltimore, Maryland. 827 pp.). Numerous species and age/size classes of waterfowl prey have been described in the diet of *C. serpentina*, such as adult *Aechmophorus occidentalis* (Western Grebe) (Igl and Peterson 2010. Waterbirds. 33:105–109), adult *Leucophaeus atricilla* (Laughing Gull) (Alexander 1921. Auk 38:596), and cygnet and adult *Cygnus buccinator* (Trumpeter Swan) (Moriarty 1990. Minnesota Herpetol. Soc. Newsl. 10:4; Lumsden 2013. Can. Field Nat. 127:138–145), among other species (see Coulter 1957. J. Wildl. Manage. 21:17–21; Ernst and Lovich 2009, *op. cit.*; Igl and Peterson 2010, *op. cit.*). Here we report predatory behavior and the first, to our knowledge, documented observation of predation of a *Mergus merganser* (Common Merganser) by *C. serpentina*.

At approximately 1000 h on 31 July 2014, an adult female *M. merganser* and five young-of-the-year juveniles were observed swimming along the shoreline of a shallow bay in Clear Lake, located in central Ontario, Canada (45.2530°N, 79.7877°W; datum WGS84). All individuals were repeatedly submerging their heads underwater, a characteristic definition of food searching behavior in *M. merganser* (Wood and Hand 1985. Can. J. Zool. 63:1260–1270). At approximately 1005 h, the female *M. merganser* was bitten on the lower right abdomen and flank by a *C. serpentina* (Fig. 1). The *M. merganser* silently struggled and beat its right wing and hind foot on the carapace and head of the *C. serpentina*. During this time, the juveniles rapidly swam away and were not observed in the bay again that day. At approximately 1007 h the *M. merganser*, with the *C. serpentina* still biting the lower flank, floated away from the shoreline and into deeper water in the bay. It, however, could not be determined which individual was instigating this movement (i.e., whether the *M. merganser* was moving on its own accord or being forcefully dragged into open water by the *C. serpentina*). Once out into deeper water, the *C. serpentina* began submerging the *M. merganser*, doing this three times over the course of approximately 10 minutes, each time holding the *M. merganser* underwater for approximately 15 seconds. In addition to maintaining a secure grip on the *M. merganser* with its jaws,

PHOTO BY C. B. BOBBIE

FIG. 1. *Chelydra serpentina* biting the lower right flank of an adult female *Mergus merganser*, Clear Lake, Central Ontario, Canada.

the *C. serpentina* used its foreclaws to hold the bird in place (as has been observed previously during oversized prey handling in *C. serpentina*; Igl and Peterson, *op. cit.*; pers. obs.). Initially the *M. merganser* struggled, beating its wings and trying to resurface when submerged. However, by the third submergence the *M. merganser* had stopped struggling. At approximately 1018 h, the *C. serpentina* again completely submerged the *M. merganser*. The bird struggled for approximately 30 seconds while underwater, released a stream of bubbles, then ceased all movement. Within 30 seconds of the bird's death, the *C. serpentina* released the bird from its jaws, abandoning the carcass, and the bird floated up to the surface of the water. We did not directly observe the *C. serpentina* consuming the *M. merganser*, however upon inspection the next day, the head and neck of *M. merganser* were gone from the body. It is unclear if this was by *C. serpentina* or a scavenger. The *C. serpentina* was not captured for measurement but was estimated to have a straight carapace length of ca. 40 cm, likely making the turtle a male (Ernst and Lovich 2009, *op. cit.*). This repeated submergence and drowning of avian prey has been documented in other instances of *C. serpentina* predation (Alexander 1921, *op. cit.*; Igl and Peterson 2010, *op. cit.*). This observation serves as a contribution towards the predatory behavior and feeding ecology of *C. serpentina*.

***CHELYDRA SERPENTINA* (Snapping Turtle). WINTER MORTALITY.** Turtles in northern latitudes may spend half the year in hibernation. Winter mortality is typically low, but overwintering can be stressful and lead to death due to freezing, prolonged anoxia, or predation (Ultsch 2006. Biol. Rev. 81:339–367). Mortality events can result in the death of many turtles. For example, 186 turtles from eight species died when a pond froze to the bottom in Iowa (Christiansen and Bickham 1989. J. Herpetol. 23:91–94).

On 6 May 2014, six adult Snapping Turtles were found dead at Mud Lake, a permanent waterbody >10 ha in size located in the Britannia Conservation Area in Ottawa, Ontario, Canada (45.371181°N, 75.794249°W, datum WGS84). There were four males (mean carapace length: 32.5 cm, range: 30.5–36.0 cm) and two females (mean carapace length: 28.8 cm, range: 27–30.5 cm). One adult male was found on shore, and the remaining turtles

were found floating just off shore along the southern margin of the lake. All of the turtles appeared to be in good condition, except for the turtle on shore which had bite marks on the head and left front shoulder, which may have occurred after death. No other species of turtle was found dead, even though >100 adult *Chrysemys picta* (Painted Turtle) are known to occur in the lake. It is unclear when the lake became ice free, but on 18 April it was still ~90% iced over.

Average monthly minimum temperatures for the winter were compared with the monthly minimum temperatures of the 30-year (1981–2010) climate normal from the Ottawa International Airport which is <10 km from Mud Lake (http://climate.weather.gc.ca/climate_normals/results_1981_2010_e.html?stnID=4337&lang=e&StationName=ottawa&SearchType=Contains&stnNameSubmit=go&dCode=1). Each month from November to April was colder than the climate normal. On average the monthly minimum temperature was 2.8°C (range: 1.0-5.7°C) colder than the 30-year climate normal. A colder than average winter could result in thicker ice causing some shallow portions of the lake to freeze to the bottom. *C. serpentina* is known to hibernate in shallow water near shore (Ultsch, *op. cit.*) and turtles in these areas may have died from freezing. Alternatively, a cold winter may have resulted in a longer than normal ice cover, causing turtles to die from prolonged anoxia. It is unknown what percentage of the adult *C. serpentina* population died. Adults were not observed less frequently in 2014, suggesting a significant portion of the population survived. It is unclear how often these kinds of mortality events occur, but dead turtles should be searched for after colder than average winters.

DAVID C. SEBURN, Seburn Ecological Services, 2710 Clarenda St, Ottawa, Ontario, K2B 7S5, Canada; e-mail: davidseburn@sympatico.ca.

***CHRYSEMYS PICTA* (Painted Turtle) and *CHELYDRA SERPENTINA* (Snapping Turtle). RAILROAD MORTALITY.** Railways can lead to turtle mortality when individuals become entrapped between rails and expire from overheating, dehydration, or train impacts (Kornilev et al. 2006. Herpetol. Rev. 37:145–148; Engeman et al. 2007. Herpetol. Rev. 38:331–332). Herein, I report observational evidence of railroad mortality in two turtle species.

On 3 June 2014, at ~1300 h, I observed a dead adult female *Chrysemys picta* in the center of a railway adjacent to wetlands in Lime Ridge, Pennsylvania, USA (41.024208°N, 76.366718°W, datum WGS84; elev. ~150 m). The turtle's carapace was partially crushed and extensive blood loss was evident. Mortality appeared to have occurred shortly before my observation. No obvious evidence of predation or scavenging was present on the *C. picta* carcass. Due to the nature of the turtle's injuries and frequent locomotive traffic along this railway (pers. obs.), it is likely that mortality resulted from direct impact with a passing train.

In August 2014, I observed the carcass of a medium-sized adult *Chelydra serpentina* in the middle of a railway adjacent to a pond in Espy, Pennsylvania, USA (41.010206°N, 76.416294°W, datum WGS84; elev. ~150 m). The *C. serpentina* carcass had experienced partial decay and desiccation. Because of the state of decomposition, it was impossible discern whether the animal experienced mortality directly from a train impact or had expired from overheating, dehydration, or predation resulting from entrapment between rails (Kornilev et al., *op. cit.*).

In Pennsylvania, *C. picta* nest in late May–June and have been noted to use rocky substrates associated with railroad beds for nesting (Hulse et al. 2001. Amphibians and Reptiles of Pennsylvania and the Northeast. Cornell Univ. Press, Ithaca, New York. 419 pp.; Bieber-Ham 2011. Population and Nesting Ecology of Painted Turtles [*Chrysemys pica*] in Pennsylvania. Honor's Thesis. Dickenson College, Pennsylvania. 37 pp.). Therefore, it is likely that the female *C. picta* became trapped between rails and expired while searching for nesting substrate associated with the railway. Likewise, female *C. serpentina* in Pennsylvania nest in late May–June and often utilize substrate associated with railways, including railway substrate near the location in which the aforementioned *C. serpentina* carcass was observed (Hulse et al., *op. cit.*; pers. observ.). Though the sex of the carcass could not be determined, this individual may have been a female that became entrapped between rails and expired during the nesting season.

I thank Brittney R. Dieter for providing literature references.

***EMYDID TURTLES.* UNUSUAL BASKING LOCATION.** Emydid turtles are most often observed basking aerially in aquatic settings (Boyer 1965. Ecology 46:99–118). Basking turtles primarily occupy deadwood structure when available (Lindeman 1998. Chelon. Conserv. Biol. 3:137–141), but will also opportunistically use other basking sites such as mammal lodges (e.g., beaver lodges; WS, pers. obs.) and anthropogenic structures (e.g., boat dock crossbeams, rope tethers; Lindeman 2013. The Map Turtle and Sawback Atlas: Ecology, Evolution, Distribution, and Conservation. University of Oklahoma Press, Norman. 460 pp.). Herein, we report an unusual basking location—an active nest of a reintroduced Whooping Crane (*Grus americana*)—used by emydid turtles in southwestern Louisiana, USA.

As part of an ongoing program to monitor the status of a Whooping Crane reintroduction in southwestern Louisiana, periodic monitoring was made of a crane nesting attempt in Avoyelles Parish (Louisiana) during Spring/Summer 2014. The nest was situated in an actively fished, commercial crawfish pond (*Procambarus clarkii*); these ponds are ephemerally flooded to promote crawfish production and often host an abundance of waterbirds (Huner et al. 2002. Waterbirds 25:66–78) and turtles (WS, pers. obs.). On 11 June 2014, a photograph was taken by SZ of the nesting crane via an aerial survey. After review of the photograph, a large emydid turtle was observed basking on the nest mound along with the incubating crane; the

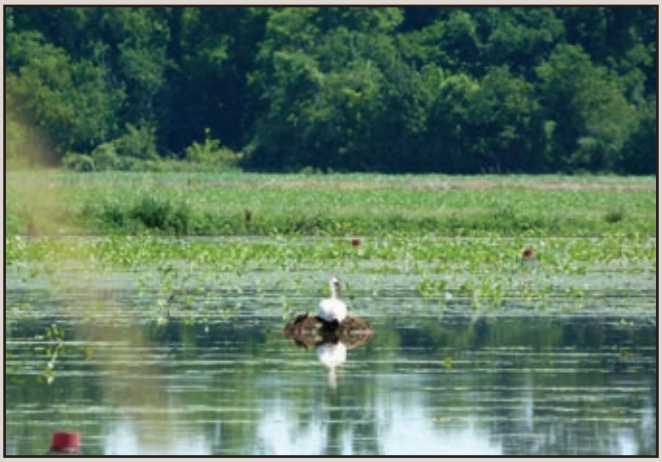

FIG. 1. Deirochelyine turtle basking on active nest of Whooping Crane in southwestern Louisiana.

turtle species could not be identified beyond family Emydidae, subfamily Deirochelyinae. On 12 June 2014, CS and CG made a second observation via ground blind of an emydid turtle basking on the nest mound (1505 h; conditions: 31°C, overcast with light rain). It was basking close to the incubating adult and remained there until 1607 h when the crane stood on the nest to preen and stretch its legs. On 20 June 2014, a third observation was documented by SZ and CS via ground blind of an emydid turtle that emerged to bask on the nest mound (1109 h; conditions: 28°C, sunny with scattered clouds). The turtle basked within 5–10 cm of the incubating crane (Fig. 1) and basked until SZ and CS left the site (1117 h).

Measurements of the nest mound by CG, CS, and SZ could not be taken until nesting had ceased (26 June 2014) to minimize disturbance and potential nest failure. The diameter of the nest measured from 92–96 cm across, with the nest mound protruding 13 cm above the water level. The water depth at the nest measured 29 cm, with mean water depth in the four cardinal directions similar to the level observed at the nest (mean = 30.3 cm, range 29–32 cm). The percent open water surrounding the nest was greater at 1 m (100%) and 5 m (100%), than at 10 m (70%).

Due to the distance between the observer and nest, the species identification was difficult to determine in all three observations beyond emydid subfamily Deirochelyinae. For the third observation, SZ took a photograph (Fig. 1) and upon closer inspection, the turtle has prominent yellow markings on the pleural scutes of the carapace and a short neck, probably eliminating *Deirochelys reticularia* (Chicken Turtle). Based on the characteristics of the turtle in the photograph, the type of habitat, and the abundance of *Trachemys scripta* (Slider) relative to *Pseudemys concinna* (Cooter) in this habitat type (WS, pers. obs.), it appears most likely to be an adult *T. scripta* of unknown sex. This is also the most likely species in observations #1 and #2, but cannot be definitively confirmed.

During these observations, both crane and turtles did not appear to show any aggression towards each other. Whooping Cranes can be quite aggressive towards other bird species and conspecifics within their nesting territory (Allen 1952. The Whooping Crane. Research Report No. 3 of the National Audubon Society. New York, New York. 246 pp.), but also readily accept other nearby birds or non-predatory mammals (Lewis 1995. *In* A. Poole [ed.], The Birds of North America Online. Cornell Lab of Ornithology; http:bna.birds.cornell.edu/bna/species/153; accessed 23 September 2014). For the turtle, however, an emergent nest mound is likely a very desirable basking substrate and similar to the characteristics of mammal lodges. These sites are desirable because they are 1) surrounded completely by water to avoid terrestrial predators; 2) the field of view is unobstructed, thereby lowering predation risks from aerial predators; and 3) it lacks vegetation and increases the thermoregulatory potential of the site early in the spring. Vegetation is thick on the surrounding levees of crawfish fields (see Fig. 1) which likely reduces its desirability as a basking site for all reasons listed above. To our knowledge, this is the first report of emydid turtles using a Whooping Crane nest as a basking site.

***EMYDOIDEA BLANDINGII* (Blanding's Turtle). JUVENILE DIET.** Adult Blanding's Turtles are known for being primarily carnivorous (reviewed by Ernst and Lovich 2009. Turtles of the United States and Canada. 2nd edition. Johns Hopkins University Press, Baltimore, Maryland. 840 pp.). For example, past reports indicate that crustaceans and insects are important dietary components, but they also consume various vertebrates and vegetation (Lagler 1943. Am. Midl. Nat. 29:257–312; Kofron and Schreiber 1985. J. Herpetol. 19:27–40; Rowe 1992. J. Herpetol. 26:111–114). Although the diet of adult Blanding's Turtles is well known, little is known about the diet of juveniles. Juveniles are secretive, and past studies have noted the difficulty in detecting/capturing them during population research (Congdon et al. 1993. Conserv. Biol. 7:826–833). The difficulty associated with capturing juvenile Blanding's Turtles poses challenges to investigation of their dietary habits. We were able to obtain dietary data on a radio-tracked juvenile Blanding's Turtle that was part of an ongoing study conducted in Rock Co., Wisconsin, USA. These findings apparently represent some of the first published data on diet and feeding ecology for a juvenile Blanding's Turtle.

A radio-tagged juvenile Blanding's Turtle (straight-line carapace length: 122.25 mm, carapace width: 89.71 mm) was removed from the field and brought into the lab on 7 July 2014, to replace a damaged transmitter (3.9 g, model PD-2, Holohil Systems Ltd., Carp, Ontario). Prior to transmitter replacement, the turtle was placed in a large plastic container partially filled with water. While in the water, the turtle defecated and was subsequently removed. The water and fecal sample were next carefully strained through a 1-mm mesh sieve to acquire all available remains from the feces. The retained fecal sample was placed in 70% ethanol to prevent degradation and later investigated. The collected remains were first separated into broad categories (i.e., belonging to an insect, or plant remnants, etc.) by sifting through them under a dissecting microscope. All invertebrate remains were further investigated under a dissecting scope and identified to taxonomic family. This was accomplished by comparing the fragments found in the fecal sample to preserved specimens of local aquatic macro invertebrates that have been previously collected and identified. Given the number of representative fragments observed, it was possible to estimate the number of individuals in each family identified.

The fecal matter contained primarily insect remains and only 2% of the discernable sample contained plant fragments. The insects identified are frequently found in wetlands, and included members of the families Dytiscidae (N = 14 larvae), Belostomatidae (N = 6; adults and various eggs), Corixidae (N = 4), Notonectidae (N = 4), adult Hydrophilidae (N = 2), and Nepidae (N = 1). Members of the families Dytiscidae, Belostomatidae, Corixidae, and Notonectidae can be found in water depths less than 30 cm (Krull 1970. J. Wildl. Manag. 34:707–718; Ward 1992. Aquatic Insect Ecology 1: Biology and Habitat, John Wiley and Sons, Inc., New York. 456 pp.). These insects are considered nektobenthic, meaning they are competent swimmers that also spend substantial time attached to the stems of submergent/emergent aquatic vegetation, rather than the sediments (Ward 1992, *op. cit.*). The insect remains found in the fecal matter contribute to a better understanding of this juvenile Blanding's Turtle's diet and where it fed. For example,

given that many of the insects consumed rest on the stems of aquatic vegetation, the juvenile turtle likely spent time feeding off of vertical structures in shallow water, rather than off of the bottom. This is consistent with the habitats where radio-tracked juveniles are typically found, which contain ample shallow water and emergent vegetation. It is noteworthy that neither hard crustacean (e.g., amphipods and juvenile crayfish) nor gastropod (e.g., snail) remains were found in the fecal sample, despite their abundance in southern Wisconsin wetlands. This is particularly interesting given that crustaceans are commonly consumed by adults (Lagler 1943, *op. cit.*; Kofron and Schreiber 1985, *op. cit.*), which suggests that juvenile and adult diets may vary. We did not find evidence of soft-bodied prey (e.g., annelids and some species of dipteran larvae), which break down prior to defecation and may have been under-represented in our sample. This note is based on one sample, and additional research on the dietary preferences of juvenile Blanding's Turtles is desirable.

***GLYPTEMYS MUHLENBERGII* (Bog Turtle) and *CLEMMYS GUTTATA* (Spotted Turtle). SHARED NEST SITE.** *Glyptemys muhlenbergii* is a federally-threatened (USFWS) species that inhabits tussock-dominated fens and other early-successional wetlands with deep mucky soil in New York State. Females tend to choose unshaded, vegetated hummocks for nesting sites, laying a clutch of 2–6 eggs (Whitlock 2002. PhD dissertation. University of Massachusetts, Amherst) in a shallow depression that they dig with their hind legs and cover with soil and vegetation. There are numerous observations of female *G. muhlenbergii* sharing hummocks or nesting cavities with conspecific females (Whitlock 2002, *op. cit.*; Janson Tesauro, Suzanne Macey, and Alvin Breisch, pers. comm.), and even ejecting an earlier-laid clutch in the process of digging and laying (A. Whitlock, pers. comm.).

On 12 June 2013, a radio-tracked female *G. muhlenbergii* was observed laying eggs in an excavated nest on the top of a hummock at approximately 1700 h in Putnam County, New York, USA (specific location withheld due to conservation concerns). At that time, there were four eggs already in the nest and she was still actively laying. The following evening, there were seven eggs in the nest, covered with a thin layer of sphagnum.

On 26 August, all seven eggs were intact within the nest. On 4 September the eggs had hatched (100% hatching success), and two hatchling turtles remained in the nest. One was a *G. muhlengergii*; the other was a *Clemmys guttata*. *G. muhlenbergii* and *C. guttata* are known to share hibernacula (Ernst 1976. J. Herpetol. 10:25–33), but to our knowledge this is the first documented instance of nest sharing between these two species.

Other species of freshwater turtle have been shown to place their eggs in microhabitats that differ from random in vegetative cover and nest temperature (Wilson 1998. Ecology 79:1884–1892). The nesting hummock observed in this instance was covered in tussock sedge, sweet flag, other forbs and sphagnum and was not directly shaded by woody shrubs. Although this is consistent with observations of other *G. muhlenbergii* nest locations, the hummock did not seem outwardly unique within this habitat, which abounds with sedge and forb-dominated hummocks. The phenomenon of multiple females using the same hummock or nest cavity, with greater numbers of hatchlings emerging over a longer time window, might predictably increase the predation risk to eggs or hatchlings (Baker et al 2013. Can. J. Zool. 91:451–461); Whitlock (2002, *op. cit.*) found depredation of Bog Turtle nests was highest in the weeks immediately following laying and later during hatchling emergence. This suggests there may be subtle cues that female turtles use to determine the suitability of a hummock that are perhaps similar in these two species, and that are more important than the increased predation risk that using common nesting spaces may create. Perhaps females are attracted to areas visited by other females, especially if similar nest-site characteristics are sought; attraction to other turtle's nests may decrease time spent searching for and testing nest sites and minimize predation risk for exposed females.

Funding for this project was through the New York State Wildlife Grants program grant T2-2-R-1 in cooperation with the U.S. Fish and Wildlife Service, Wildlife and Sport Fish Restoration Program.

***GOPHERUS POLYPHEMUS* (Gopher Tortoise). NEST AND BURROW DEFENSE.** *Gopherus polyphemus* lives in underground burrows and females often deposit their eggs within the bare sand "apron" at their burrow entrance. *G. polyphemus* has been documented guarding their nests from humans during daylight hours (Grosse et al. 2012. Chelon. Conserv. Biol. 11:148–151) but to our knowledge, defensive behavior has not been documented with non-human predators, or at night. Although not native to the southeastern United States, natural dispersal and translocation by humans since the early 1900s (Fitch et al.1952. J. Mammal. 33:21–37) have drastically expanded the range of *Dasypus novemcinctus* (Nine-banded Armadillo), and it is now abundant throughout much of the Southeast. The following observations of nest and burrow defense occurred at the Joseph W. Jones Ecological Research Center in Baker Co., Georgia, USA.

During the 2014 *G. polyphemus* nesting season, as part of a study on nest predation, we used motion sensing trail cameras (UWAY VH400HD, Norcross, Georgia) to monitor 24 active tortoise burrows (Auffenberg and Franz 1982. *In* R. B. Bury [ed.], North American Tortoises: Conservation and Ecology, pp. 95–126. USDI Fish and Wildlife Service Wildlife Research Report 12) containing artificial nests constructed with chicken eggs and 16 active burrows containing natural tortoise nests. The cameras detected *G. polyphemus* exhibiting aggressive behavior toward *D. novemcinctus* at four (10%) monitored nests. Between 19 June and 20 June 2014 from 2050 to 0210 h, we recorded a female *G. polyphemus* exhibiting aggressive behavior in defense of her burrow, which contained a natural nest (located ~20 cm from the burrow entrance and 15.2 cm below ground) from a *D. novemcinctus*. This tortoise was observed on video lunging toward the *D. novemcinctus* and attempted to bite, but did not leave the entrance of the burrow. Despite the behavior of the tortoise, the *D. novemcinctus* fully depredated the nest during this event. We documented this behavior a second time with a different tortoise of unknown gender on 16 July 2014 at 0558 h. This tortoise was successful in driving the *D. novemcinctus* away from the burrow, and the nest (located ~27 cm from the burrow

entrance and 16 cm below ground) subsequently hatched on 8 October 2014.

On 15 July and 19 July 2014 at 0500 and 0434 h, respectively, we documented two additional *G. polyphemus* exhibiting aggressive behavior toward *D. novemcinctus*. These tortoises were filmed at the entrance of their burrows lunging toward a *D. novemcinctus*, but to our knowledge, no natural tortoise nest was present at their burrows. However, *D. novemcinctus* may have been attracted to these burrows because they contained artificial nests, but we do not expect that the presence of an artificial nest would alter the resident tortoise's behavior. Our observations indicate that *G. polyphemus* defend their burrows and possibly their nests from *D. novemcinctus*.

MICHELINA C. DZIADZIO (e-mail: mdziadzi@jonesctr.org) and **LORA L. SMITH**, Joseph W. Jones Ecological Research Center, 3988 Jones Center Drive, Newton, Georgia 39870-8522, USA.

***GRAPTEMYS SABINENSIS* (Sabine Map Turtle). KYPHOSIS.** Kyphosis has been described in a number of chelonian species with most occurring in cryptodirans (Rhodin et al. 1984. Brit. J. Herptetol. 6:369–373; Trembath 2009. Chelon. Conserv. Biol. 8:94–95). Among *Graptemys*, kyphosis had previously only been observed in *G. oculifera* (Ringed Sawback; Selman and Jones 2012. Chelon. Conserv. Biol. 11:259–261). During riverine turtle population studies in southwestern Louisiana, two female *G. sabinensis* exhibiting kyphosis were captured in fyke nets, the first records of kyphosis for the species.

Female #1 was captured near Estherwood, Louisiana, USA (30.2027°N, 92.4886°W; datum WGS84) on Bayou Plaquemine Brule, a tributary of the Mermentau River on 28 August 2013 with a midline plastron length (MPL) of 10.9 cm, a carapace height (CH) of 6.6 cm, and a mass of 265 g (Fig. 1A). Female #2 was captured near Mermentau, Louisiana, USA (30.1729°N, 92.9010°W; datum WGS84) on the Mermentau River on 5 September 2013 with an MPL of 16.6 cm, a CH of 9.4 cm, and a mass of 1050 g (Fig. 1B). The deformity of Female #2 also included slight scoliosis (left lateral curvature of the spine at vertebral 2 and 3) suggestive of kyphoscoliosis. Female #1 possessed no additional physical abnormalities (Fig. 1A), while Female #2 had several carapacial scute abnormalities (14 left and 13 right marginal scutes, 6 vertebral scutes, and 5 left plural scutes) and severe damage to the rear plastron (Fig. 1B).

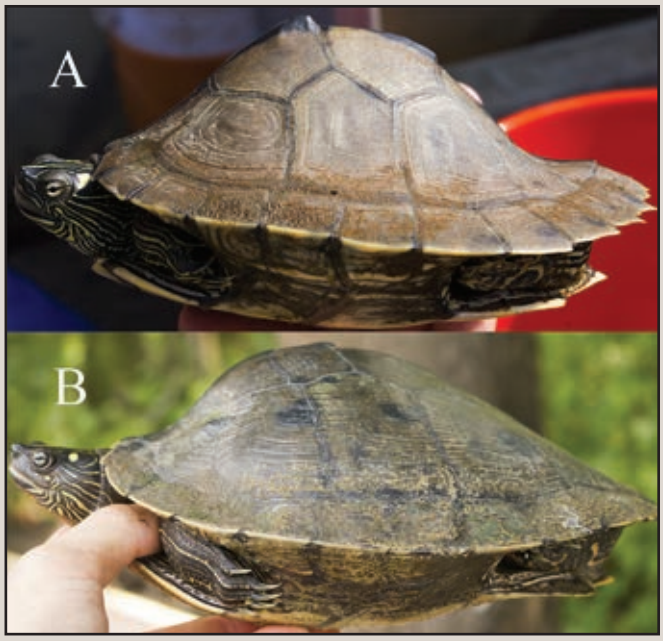

FIG. 1. A) Kyphotic *Graptemys sabinensis* female #1 captured on Bayou Plaquemine Brule near Estherwood, Louisiana. B) Kyphotic female #2 captured on the Mermentau River near Mermentau, Louisiana.

These individuals represented 0.93% of the 216 *G. sabinensis* captured in the Mermentau drainage and 0.38% of the 530 *G. sabinensis* caught across the Sabine, Calcasieu, and Mermentau rivers. The prevalence of kyphosis in *G. sabinensis* appears high relative to other turtle studies documenting kyphosis: 0.10% of 3830 *G. oculifera* (Selman and Jones, *op. cit.*), 0.06% of 21,786 *Trachemys scripta* (Tucker et al. 2007. Herpetol. Rev. 38:337), 0.36% of 833 *Emydura macquarii* (Trembath, *op. cit.*). However, larger sample sizes from the Sabine and Calcasieu rivers would be needed to compare kyphosis prevalence across drainages because kyphosis is rare and our sample sizes were small compared to other studies.

***KINOSTERNON BAURII* (Striped Mud Turtle). AUTOHIRUDINOPHAGY.** Ecological interactions between turtles and leeches (Hirudinea) are typically viewed in the context of host-parasite relationships (Telford 1984. *In* G. Hoff et al. [eds.], Diseases of Amphibians and Reptiles, pp. 385–518. Plenum Press, New York; Brown et al. 1994. Copeia 1994:228–231; Raedel et al. 2008. Copeia 2008:227–233). However, leeches have also been documented as prey for some chelonians (e.g., *Chelydra serpentina*, *Chrysemys picta*, *Emydoidea blandingii*, *Graptemys ouachitensis*, *G. versa*, *Kinosternon flavescens*, *Macrochelys temminckii*, *Sternotherus odoratus*; Ernst and Lovich 2009. Turtles of the United States and Canada. Johns Hopkins University Press, Baltimore, Maryland. 827 pp.). When observed, these predatory interactions involved turtles consuming leeches that were not attached to a host (Ernst 1986. J. Herpetol. 20:341–352) or turtles of one species (*C. picta*) biting leeches that were attached to turtles of another species (*C. serpentina*) (Krawchuck et al. 1997. Can. Field Nat. 111:315–318). Herein, we describe observations of two *Kinosternon baurii* consuming leeches (*Placobdella parasitica*) attached to their own bodies.

On 1 June 2014 at approximately 1500 h, we captured one adult male (80 mm CL) and one adult female (62 mm CL) *K. baurii* in a pond on the Santa Fe College campus in Gainesville, Florida, USA (29.68279°N, 82.43869°W, WGS84; elev. 52 m) as part of a long-term mark-recapture study. Prior to measuring the turtles, we observed their behavior while they were temporarily housed in a plastic container (65 x 43 x 39 cm) filled with pond water to a depth of approximately 10 cm. At 1545 h, we observed the male bite at his own right hind limb and consume an attached leech. The male then fully extended his neck, turned his head 180°, and bit at the skin beneath the anterior edge of his carapace two times, each time consuming an attached leech. At 1555 h, we observed the female also extend her neck, turn her head 180°, and consume four leeches attached to the skin near the anterior edge of her carapace. Our observations represent the first report of

leeches in the diet of *K. baurii* and the first report of this species eating leeches attached to its own body. We term this behavior autohirudinophagy. Bourque (2011. Herpetol. Rev. 42:232–234) reported two captive *Sternotherus minor* removing leeches from their shells and limbs but could not tell if they were consumed; some leeches were attached to the inside of their mouths. No leeches remained in the mouths of the *K. baurii* we observed. Novelli et al. (2009. Herpetol. Rev. 40:435–436) observed four Brazilian Snake-necked Turtles (*Hydromedusa maximiliani*) removing dead skin and turbellarian ectosymbionts from their own axillary and inguinal pockets in the laboratory. Consumption was not noted. Atmospheric and terrestrial basking that may aid in ectoparasite removal only rarely occur in these species (Ernst and Lovich 2009; Novelli et al., *op. cit.* and references therein; Mitchell and Johnston 2012. Herpetol. Rev. 43:127). Autohirundinophagy and grooming may be alternatives to using basking as a means of removing leeches and skin in bottom-walking turtles that seldom bask (Novelli et al., *op. cit.*; this study).

***KINOSTERNON HIRTIPES* (Rough-footed Mud Turtle). MAXIMUM SIZE AND HABITAT.** *Kinosternon hirtipes* occurs from extreme western Texas, south into northern and central Mexico (Ernst and Lovich 2009. Turtles of the United States and Canada. 2nd edition. Johns Hopkins University Press, Baltimore, Maryland. 827 pp.). In Texas, *K. hirtipes* is restricted to the Alamito Creek drainage in Presidio Co. and classified as a threatened species by the Texas Parks and Wildlife Department owing to its limited distribution and continuing habitat degradation (Texas Parks and Wildlife Department 2013. Species of Conservation Concern. Available from: www.tpwd.state.tx.us). *Kinosternon hirtipes* is considered among the least-studied of North American turtles and very little is known concerning its natural history (Ernst and Lovich, *op. cit.*; Lovich and Ennen 2013. Amphibia-Reptila 34:11–23). We here report a new maximum size record for *K. hirtipes* and describe the habitat where this turtle was captured.

On 9 March 2013, one of us (JLS) captured a large male *K. hirtipes* in a double-throated wire mesh trap (1 m long × 30 cm wide) baited with canned sardines (packed in soybean oil) and set in a livestock pond located on a private ranch approximately 57 km SE of the town of Marfa, Texas. The straight-line carapace length (CL) of this turtle measured 195 mm; other measurements were: carapace width = 120 mm; plastron length = 145 mm; plastron width = 78 mm; shell depth = 80 mm; body mass = 982 g. Because the plastral annuli were worn and no longer visible, we were unable to estimate the age of this turtle (Iverson et al. 1991. J. Herpetol. 25:64–72). The turtle was permanently marked by notching a unique series of marginal scutes (Cagle. 1939. Copeia 1939:170–173) and released about 10 minutes after being captured and measured. The CL of this turtle exceeds the previously reported size maximum for *K. hirtipes* (CL = 185 mm; Ernst and Lovich, *op. cit.*) by 10 mm. Furthermore, the CL of this turtle is considerably larger than the asymptotic CL of 188 mm calculated by Platt et al. (unpubl.) for a sample (N = 27) of recaptured *K. hirtipes* from another wetland in the Alamito Creek drainage.

The pond (elevation approximately 1100 m) where the record-sized turtle was captured is a spring-fed natural wetland within the Alamito Creek drainage that was modified by damming to provide water for livestock. The pond is steep-sided with an estimated surface area of 6418 m^2 and averages 5.0 m deep; the substrate is mud. Because the pond is fed by an artesian spring, water levels remain relatively constant throughout the year, even under drought conditions. Water temperature ranged from a high of 23.7°C in summer to a low of 15.8°C in winter. The water is relatively clear and the bottom of the pond (5 m) is readily visible; Secchi depth was measured at 5.0 m. The pond supports dense stands of emergent aquatic vegetation (*Scirpus*, *Typha*, and Poaceae) and approximately 30% of the surface area is dominated by *Typha*. Notably, this is one of the few ponds in the area to support dense stands of *Typha*, which are typically eradicated by landowners to maintain open water. Mats of *Chara* and filamentous algae are present in open water. The surrounding landscape was formerly arid grassland (Wilde and Platt 2011. J. Big Bend Studies 23:85–106), but is now dominated by Honey Mesquite (*Prosopis glandulosa*) and Creosote Bush (*Larrea tridentata*). In addition to the record-sized *K. hirtipes*, five other large adult males (mean CL ± 1SD = 166 ± 8.8 mm; range = 156–178 mm), but no females were trapped in this pond from 2011 through 2014 as part of an on-going population study (Smith et al., unpubl. data). The nearest other pond known to harbor *K. hirtipes* is located approximately 8.7 km away. There is no connectivity between these populations, which are isolated by intervening desert landscape. Populations of Red Shiner (*Cyprinella lutrensis*), sunfish (*Lepomis* spp.), largemouth bass (*Micropterus* spp.), and catfish (Siluriformes) are present in the pond after having been stocked for recreational fishing by the landowner; the latter two fish represent likely predators of neonate and hatchling *K. hirtipes*. Although Yellow Mud Turtles (*Kinosternon flavescens*) are present in both ephemeral and permanent waterbodies in the Alamito Creek drainage (Platt et al., unpubl. data), none were captured in the pond during four years of trapping.

There are few other published descriptions of *K. hirtipes* habitat for comparison to our data. Iverson et al. (*op. cit.*) found a large population of *K. hirtipes* inhabiting a springfed stream flowing through arid grassland in Chihuahua, Mexico. The stream was described as clear and fast-flowing, 100–200 cm wide (average width = 100 cm) and 10–100 cm deep (average depth = 50 cm) with a sand-gravel substrate and deeply undercut banks where turtles sought refuge. Dense stands of *Typha* were established along the bank in backwater areas where the current was reduced. Similarly, Ernst and Lovich (*op. cit.*) describe a population of *K. hirtipes* inhabiting a livestock pond in Texas (480 m^2 and 4.0 m deep) that was "choked" with muskgrass (*Chara* sp.). Collectively, these reports and ours suggest that springfed permanent wetlands with an abundance of submerged and emergent aquatic vegetation are required by *K. hirtipes*. Additional ecological studies of this poorly known species are warranted.

Turtles were collected under a Scientific Research permit (SPR-0307-844) issued to SGP by the Texas Parks and Wildlife Department. We thank the various landowners in Presidio County, Texas for allowing us to study turtles on their properties. Support for SGP was provided by Wildlife Conservation Society. Comments by Lewis Medlock improved an early draft of this manuscript.

***LISSEMYS PUNCTATA VITTATA* (Indian Flapshell Turtle). CLUTCH SIZE.** The clutch size of *Lissemys punctata* sensu lato is reported to be 2–15 (Bhupathy et al. 2014. *In* Rhodin et al. [eds.], Conservation Biology of Freshwater Turtles and Tortoises: A Compilation Project of the IUCN/SSC Tortoise and Freshwater Turtle Specialist Group. Chelonian Research Monographs No. 5, pp. 076.1–12). However, little is known of the reproductive attributes of *Lissemys punctata vittata*, a subspecies occurring in peninsular India. Four specimens of *L. punctata vittata* were confiscated by authorities in Kolkata, West Bengal, on 12 December 2014 and were housed at the Wildlife Rescue Centre (Saltlake), Kolkata. On 18 December 2014 at ca. 1830 h we found a clutch containing 12 eggs in the turtle's enclosure. Egg diameter ranged from 26.06–30.24 mm (mean = 27.68 mm) and the weight ranged from 10.8–14.6 g (mean = 12.45 g). We kept the eggs in a batch of six in two plastic boxes with vermiculite as substrate for artificial incubation. Unfortunately, facilities to maintain suitable incubation temperatures for the eggs were lacking at the rescue center and the eggs appeared non-viable. We thank the Forestry Department of West Bengal for their co-operation.

***MALACLEMYS TERRAPIN LITTORALIS* (Texas Diamond-backed Terrapin). SOCIAL OR GROUP BURROWING.** Social behavior in turtles is often seemingly related to limited resources, and is presumably beneficial if it increases mating success or access to resources. For example, Snapping Turtles (*Chelydra serpentina*) display territorial behavior that may allow them to defend resources and potential mates (Galbraith et al. 1987. Can. J. Zool. 65:2623–2629). *Malaclemys terrapin* has been observed participating in mating aggregations (Hauswaldt and Glenn 2005. Mol. Ecol. 14:723–732) and lekking (Estep 2005. Thesis: College of Charleston), however, social burrowing behavior has not been reported to date.

We observed "social burrowing" behavior of *Malaclemys terrapin littoralis* during an ongoing mark-recapture population monitoring study on South Deer and North Deer Islands, as well as in a marsh along Sportsman's Road on Galveston Island, in West Galveston Bay, Texas, USA between 2010–2011. A literature review indicates that this is the first reported occurrence of social or group burrowing in *M. terrapin littoralis*. Burrows were found during randomized terrestrial line transects and varied in location between creek beds, lowland frequently-submerged marsh, and upland vegetated marsh. These burrows were typically located in a natural occurring depression in the marsh, but were also dug by the terrapins in a few cases. We observed social burrows during December through September, but did not locate any social burrows in October and November. Burrows contained 3–15 terrapins, and sex ratios in the burrows varied between months. Sex ratios favored females in every month with the exception of September, with the average number of females being more than double the average number of males from May through August. In some cases, groups of individual terrapins were recaptured together in separate burrowing events. Spatial and temporal distribution of burrows did not appear to be related to available habitat and resources, such as vegetation density, composition, or distance from water. This suggests that these burrows could potentially be indicative of mating aggregations rather than a resource-dependent behavior. We found that 95% of the burrows occurred less than 6.5 m from a waterbody, which includes the open bay as well as tidal creeks within the interior of South Deer island,, and that the average vegetation cover at the site of the burrow was 71.8%. Females found in these social burrows were frequently gravid as determined with ultrasound imaging. On average, we observed more terrapins per burrow in August and a greater number of burrows in June compared to other months.

Further investigation into the cause and temporal and spatial distribution of these social burrows is desirable. Any trends we observed were statistically insignificant, which was mainly due to small sample size and high variance. Discovering the cause of social burrowing could increase our understanding of terrapin mating and social behavior, and could help us better describe key habitats for conservation.

***MANOURIA EMYS PHAYREI* (Asian Brown Tortoise). FIRE SCARRING.** Fire scars on turtle shells result from burn injuries sustained during exposure to the extreme heat of fires (Ernst et al. 1995. Herpetol. Rev. 26:185–187; Dodd et al. 1997. Herpetol. Nat. Hist. 5:66–72). Fire scars are characterized by an obvious blanching of the scutes caused by damage and subsequent repair of the keratin layers (Dodd et al., *op. cit.*). Regeneration after severe fire injuries can result in complete disappearance of sutures between the scutes, as well as extensive remodeling and gross distortion of the underlying bone (Dodd et al., *op. cit.*). Fire scars can occur anywhere on the shell, but are most commonly observed on the carapace (Mitchell et al. 2005. Herpetol. Rev. 36:169). Fire scars have been reported on the shells of various chelonians in Southeast Asia, including *Sibenrockiella crassicollis* (Mitchell et al., *op. cit.*), *Cuora amboinensis* (Platt et al. 2001. Chelon. Conserv. Biol. 4:154–159; Ives et al. 2008. Chelon. Conserv. Biol. 7:240–248), *Melanochelys trijuga* (Mitchell and Rhodin 1996. Chelon. Conserv. Biol. 2:66–72), *Geochelone platynota* (Platt et al. 2003. Oryx 2:66–72), and *Indotestudo elongata* (van Dijk. 1998. The Natural History of the Elongated Tortoise *Indotestudo elongata* [Blyth, 1853] [Reptilia: Testudines] in a Hill Forest Mosaic in Thailand, with Notes on Sympatric Turtle Species. Ph.D. dissertation, National University of Ireland at Galway. 255 pp.; Platt et al. 2001. Chelon. Conserv. Biol. 4:172–177). We here report on the incidence of fire scarring among a group of adult *Manouria emys phayrei* held at two conservation-breeding facilities (assurance colonies) in Myanmar.

These *M. emys* were originally confiscated by the Myanmar Forest Department from illegal wildlife traffickers in 2007. Although their specific provenance could not be determined, given our understanding of regional wildlife trafficking networks (Platt et al. 2000. Chelon. Res. Monogr. 2:95–100), we believe the tortoises were harvested within Myanmar, most likely from the western hill tracts (Rakhine [= Arakan] and Chin Hills) or southern Tanintharyi Region (formerly "Division"); however, we cannot rule out the possibility that some members of this group originated in neighboring countries (e.g., Bangladesh or Thailand). After confiscation the tortoises were housed in outdoor pens at the Yadanabon Zoological Gardens in Mandalay

FIG. 1. An extreme case of fire scarring on an adult male *Manouria emys phayrei* (CL = 417 mm) confiscated from wildlife traffickers in Myanmar.

FIG. 2. A partially buried adult *Manouria emys phayrei* at an assurance colony in Myanmar. This concealment behavior may explain the distribution of fire scars on the carapace of many burned *M. emys*.

from 2007 through early 2013. Because ambient environmental conditions in this extremely arid region of Myanmar proved unsuitable for *M. emys*, new facilities were constructed in Gwa (Rakhine State) and Maymyo (Shan State) where the prevailing climate is more appropriate for the propagation of this forest-dwelling tortoise (Chan-ard et al. 1996. Chelon. Conserv. Biol. 2:109–113).

In May 2013, prior to transferring *M. emys* into the new assurance colonies, we weighed, measured (straight-line carapace length [CL]), and permanently marked each individual. We also carefully inspected the carapace and plastron of every tortoise for shell damage. Seven (12.2%) of 57 tortoises (25 males and 32 females) exhibited shell damage consistent with published descriptions of fire scarring (Rose 1986. Southwest. Nat. 31:131–134; Ernst et al., *op. cit.*; Dodd et al., *op. cit.*). To our knowledge, this is the first report of fire scarring among *M. emys*. Fire scarring was noted on the shells of three females (CL = 481–504 mm) and four males (CL = 399–472 mm), and varied from a few blanched and discolored scutes to extensive remodeling and ossification of the carapace. In the most extreme case, an adult male (CL = 417 mm) exhibited fire damage over >50% of its carapace; sutures between most costal and marginal scutes had disappeared, the anterior-most marginal scutes were missing, and massive distortion of bony carapacial elements was evident (Fig. 1).

Fire scars on the other six tortoises were located on the medial and posterior regions of the costal and vertebral scutes; some distortion of the sutures was noted in four individuals. The marginal scutes of three of these six tortoises also exhibited fire scarring, but in two cases the damage appeared minor and consisted of discoloration or loss of keratinized laminae; only one tortoise had damage to the underlying bone. Another tortoise also had patches of exposed bone on the costal and vertebral scutes where the laminae apparently failed to regenerate over parts of the fire-damaged carapace. For the most part, fire scarring was confined to the carapace of tortoises; however, plastral scarring was observed in two individuals. In one tortoise, a small area of exposed bone on the distal edge of the left pectoral scute appeared associated with minor fire scarring on the adjacent plastral bridge. A second tortoise with fire scars on the rearmost vertebral and three left costals, exhibited plastral damage at the junction of the right pectoral and abdominal scutes, although this did not appear to be the result of a fire injury.

The pattern of fire scars on tortoise shells that we observed is probably best explained by the concealment behavior of *M. emys*. In the assurance colonies we frequently find *M. emys* partially buried in loose soil with only the upper part of the carapace exposed aboveground (Fig. 2). This behavior seems especially commonplace during the dry season (mid-November through late May) and probably both reduces evaporative water loss and confers protection from fires. Should a brushfire pass over the buried tortoise, the costal and vertebral scutes would seem most likely to sustain fire injuries, while the buried plastron and marginal scutes would not be exposed to flames. By withdrawing the head and legs into the shell, the tortoise would also avoid soft tissue burns.

Our observations of fire scarring suggest that wildfires pose a danger to *M. emys* in Myanmar and perhaps elsewhere within its geographic distribution. Fire has not previously been considered a threat to *M. emys* because these tortoises generally inhabit tropical evergreen forests (Thirakhupt and van Dijk 1994. Nat. Hist. Bull. Siam Soc. 42:207–259; Chan-ard et al., *op. cit.*), which are not prone to natural burning except under extremely dry conditions that infrequently occur during the dry-wet season transition when lightning strikes can cause ignition (Stott 1988. Geogr. J. 15:337–350). Because tropical evergreen forests rarely burn under natural conditions, most fires in *M. emys* habitat are thought to be anthropogenic in origin, resulting from the deliberate ignition of dried fuels by shifting agriculturalists, pastoralists, and hunters (Rabinowitz 1990. Nat. Hist. Bull. Siam Soc. 38:99–115; Platt et al. 2010. Bamboo Sci. Cult. 23:1–12).

How anthropogenic burning might impact *M. emys* at the population level remains unknown, reflecting in part, a general paucity of information on the fire ecology of chelonians (Russell et al. 1999. Wildl. Soc. Bull. 27:374–384). However, there is no doubt that on occasion, fires cause significant mortality among populations of terrestrial chelonians (Platt et al. 2010. Nat. Areas J. 30:254–260). For example, in Florida, USA, fire-related mortality among *Terrapene carolina bauri* inhabiting pine forests subjected to different prescribed burning regimes ranged from

10.2 to 21.6%, depending on season (Platt et al. 2010, *op. cit.*). In Southeast Asia where anthropogenic burning is common during the dry season (Mitchell et al., *op. cit.*), fire-related mortality has been documented in *Geochelone platynota* (Platt et al. 2003, *op. cit.*), *Indotestudo elongata* (Thirakhupt and van Dijk, *op. cit.*), *I. forstenii* (Platt et al. 2001. Chelon. Conserv. Biol. 4:154–159), and *Melanochelys trijuga* (Mitchell and Rhodin 1996. Chelon. Conserv. Biol. 2:66–72). Although reports of fire-caused mortality appear lacking for *M. emys*, the extent of fire scarring we observed in one individual suggests that such injuries at least occasionally result in death. Because the ability of turtle populations to withstand even moderate levels of increased mortality among larger size classes is doubtful (Congdon et al. 1993. Conserv. Biol. 7:826–833; Congdon et al. 1994. Amer. Zool. 34:397–408), mortality due to anthropogenic burning together with over-harvesting and habitat destruction potentially threatens the continued survival of *M. emys* in Myanmar.

We thank the Ministry of Environmental Conservation and Forestry for granting us permission to conduct research in Myanmar. Continuing support for assurance colonies has been provided by Turtle Survival Alliance and Wildlife Conservation Society. Additional support for SGP was provided by Andy Sabin and the Sabin Family Foundation. We thank Deb Levinson and the library staff at Wildlife Conservation Society, and Peter Paul van Dijk for literature. Comments by Lewis Medlock improved an early draft of this manuscript. The findings and conclusions in this article are those of the authors and do not necessarily represent the views of the U.S. Fish and Wildlife Service.

***STERNOTHERUS ODORATUS* (Eastern Musk Turtle). FORAGING AND DIET.** Eastern Musk Turtles are known omnivores, eating a variety of both live and dead animal prey, from beetles to tadpoles and fish, as well as algae and fleshy-leaved plants and fruits (Ernst and Lovich 2009. Turtles of the United States and Canada, 2nd edition. Johns Hopkins Press, Baltimore, Maryland. 827 pp.). Seeds of many *Pinus* species are eaten by game birds, rabbits, squirrels, and chipmunks, as well as by coyotes and black bears (Petrides 1986. A Field Guide to Trees and Shrubs, 2nd edition. Houghton Mifflin Co., Boston, Massachusetts. 464 pp.). To the best of our knowledge, herein we document the first report of an Eastern Musk Turtle consuming seeds from a pine tree.

On 21 October 2014 at 1448 h we observed a young adult Eastern Musk Turtle of unknown sex swimming at the surface of a small pond on Charlie Elliott Wildlife Center, 6.7 km S of Mansfield, Jasper Co., Georgia USA (3.45868°N; 83.72326°W; WGS 84). The turtle began to actively chase after and consume the drifting Loblolly Pine (*Pinus taeda*) seeds that were floating at the surface. The turtle approached each seed from below and grabbed it with its jaws, wresting it from the papery samara that allowed the seed to float. The turtle then slowly sank down to the pond bottom where it appeared to crush the seed before swallowing. In this manner the turtle was observed to consume approximately a dozen seeds over the course of three or four minutes.

BERKELEY W. BOONE, **AMBER MOONEY**, and **JAMES MURDOCK**, Georgia Department of Natural Resources, Charlie Elliott Wildlife Center, 543 Elliott Trail, Mansfield, Georgia 30055 USA (e-mail: bboone@dnr.state.ga.us).

***TERRAPENE CAROLINA* (Eastern Box Turtle). DIET.** *Terrapene carolina* consumes a variety of food including insects, plants, and fungi (Strang 1983. J. Herpetol. 17:43–47). Mushrooms have been noted as a common source of food (Stickel 1950. Ecol. Monogr. 4:351–378); however, most published investigations on *T. carolina* consumption of mushrooms fail to identify the mushroom species. The few mushroom species noted in publications include *Russula* spp., *Leccunum scaber*, *Amanita vaginata*, and *Cyathus striatus* (Nichols 1917. Copeia 46:66–88; Dodd 2002. North American Box Turtles: A Natural History. University of Oklahoma Press, Oklahoma. 231 pp.). On 15 July 2014, an adult female *T. carolina* was found consuming a large Bicolored Bolete mushroom (*Boletus bicolor)* in Madison Co., Kentucky, USA (37.57252°N, 84.22002°E, WGS84; elev. 262 m). *Boletus bicolor* is a non-toxic mushroom that is found in eastern North America and is hosted by the Northern Red Oak (*Quercus rubra*) (Homola and Mistretta 1977. Maine Agric. Exp. Sta. Bull. No. 735). We believe this represents the first documented case of *B. bicolor* being consumed by *T. carolina.*

We thank S. Bec for identifying *B. bicolor* and K. Dodd for providing insights into *T. carolina* mushroom consumption.

PRICE**, Department of Forestry, University of Kentucky, Lexington, Kentucky 40506, USA (e-mail: steven.price@uky.edu).

CROCODYLIA — CROCODILIANS

***CROCODYLUS ACUTUS* (American Crocodile). DIET.** Crocodilians are considered opportunistic hunters due to their consumption of a wide variety of prey items (Magnusson et al. 1987. J. Herpetol. 21:85–95). Platt et al. (2013. J. Herpetol. 47:1–10) reported the diet of *Crocodylus acutus* in coastal Belize includes insects, birds, amphibians, reptiles, fish, mollusks, and crustaceans (see also Villegas and Schmitter-Soto 2008. Acta Zool. Mex. 24:117–124). Several species of crocodilians, including *C. acutus*, also deliberately ingest fruits (Platt et al. 2013. J. Zool. 291:87–99). Neonates are opportunistic predators (Platt et al. 2002. Herpetol. Rev. 33:202–203) and are largely insectivores (Davenport 2013. Treat. Est. Coast. Sci. 6:227–249), but also eat crustaceans and small fish (Mazzotti 1983. PhD diss. Pennsylvania State University. 161 pp). Magnusson et al. (1987. J. Herpetol. 21:85–95) reported that Amazonian crocodilians consume isopods, and Platt (2013. J. Herpetol. 47:1–10) revealed that *C. acutus* in Belize also consume isopods; however, neither identified this prey item to genus. Here we report the first confirmed evidence of a hatchling *C. acutus* consuming a crustacean from the order Isopoda within the genus *Ligia.*

While collecting data for an ongoing *C. acutus* ecology study on 9 August 2013 at approximately 2115 h, a hatchling *C. acutus* was captured in coastal mangrove habitat of Florida Bay, Everglades National Park, Florida, USA (25.1749°N, 80.6433°W). The hatchling was feeding on a small isopod of the genus *Ligia* (Fig. 1) while researchers collected morphometric data. After

FIG. 1. Hatchling *Crocodylus acutus* feeding on an isopod of genus *Ligia*.

FIG. 1. *Leopardus wiedii* preying on an adult *Ameiva ameiva*.

approximately 5 minutes, the crocodile released the isopod. This organism was further narrowed down to two possible species, *L. baudiniana* or *L. exotica*, however it could not be positively identified to species as the photograph provided (Fig. 1) did not show enough key identifying characteristics (William Kern, pers. comm.).

SETH FARRIS (e-mail: SethCFarris@gmail.com), **MICHIKO SQUIRES**, **JEFFREY S BEAUCHAMP**, and **FRANK MAZZOTTI**, University of Florida, Ft Lauderdale Research and Education Center, 3205 College Ave, Davie, Florida 33314, USA.

SQUAMATA — LIZARDS

***AMEIVA AMEIVA* (Green Ameiva). PREDATION.** The medium-sized terrestrial teiid lizard *Ameiva ameiva* (up to ca. 170 mm SVL) is widely distributed throughout South America, occurring in both open and forested biomes (Vitt and Colli 1994. Can. J. Zool. 72:1986–2008; Ugueto and Harvey 2011. Herpetol. Monogr. 25:113–170). On 18 January 2006, during the afternoon, one of us (RBN), witnessed the predation of an adult *A. ameiva* by a Margay Cat, *Leopardus wiedii* (Fig. 1), in Lagoa Santa farm (17.649167°S, 40.352778°W), municipality of Nanuque, state of Minas Gerais, Brazil. This site contains fragments of Atlantic Rainforest surrounded by *Eucalyptus* plantations.

The Margay is widely distributed from northern Mexico through Central and South America south to NE Argentina, southern Brazil, and Uruguay (Eizirik et al. 1998. J. Mol. Evol. 47:613–624). Margays prey mainly on small mammals and birds, but occasionally also on frogs, lizards, and snakes (Wang 2002. Stud. Neotrop. Fauna Environ. 37:207–212; Rocha-Mendes et al. 2010. Biota Neotrop. 10[4]:21–30; Bianchi et al. 2011. Zoologia 28:427–435; Cinta-Magallón et al. 2012. Cuad. Invest. UNED 4:33–40). Regarding predation on squamate reptiles, those studies (which were mostly based on analyses of scats) did not give precise identification of the prey, with only one (Cinta-Magallón et al., *op. cit.*) providing identification to genera and (tentatively) to species. The present note documents the first record of predation on *A. ameiva* by *L. wiedii*. Although Margays are widely regarded as primarily arboreal felids, there is increasing evidence (including the present report) that they may forage on the ground and prey on terrestrial vertebrates frequently (Cinta-Magallón et al., *op. cit.*; Wang, *op. cit.*; T. G. de Oliveira, pers. comm.).

We thank Tadeu G. de Oliveira, Rita de Cássia Bianchi, and Flávio Henrique G. Rodrigues for confirming the identification of the felid. T. G. de Oliveira also contributed with some information on the behavior of margays.

***ANOLIS AHLI* (Ahl's Anole). MAXIMUM ELEVATION.** *Anolis ahli* is distributed in Sierra de Trinidad, central Cuba (Rodríguez-Schettino 1999. The Iguanid Lizards of Cuba. University Press of Florida, Gainesville. 428 pp.) within an elevational range of 250–800 m elev. (Estrada 1994. Rev. Acad. Colomb. Cienc. 19:353–360). Herein we report a higher elevation record for *A. ahli*. On 4 October 2013 a specimen of *A. ahli* (MFP 12514: Felipe Poey Natural History Museum, Havana, Cuba) was collected on Pico San Juan (21.9890°N, 80.1475°W; NAD27), Cienfuegos Province, Cuba, at 1030 m elev. This new record is over 230 m higher than the previous record (Estrada, *op. cit.*). Pico San Juan, at 1140 m elev., is the maximum elevation in central Cuba.

We thank Julio León, Raimundo López-Silvero, and Leosveli Vasallo for field assistance, and the Cienfuegos Botanical Garden for logistical support.

RODRÍGUEZ-CABRERA**, Jardín Botánico de Cienfuegos, Cienfuegos, Cuba (e-mail: tomasmichel.rodriguez@gmail.com).

***ANOLIS GUAMUHAYA* (Escambray Bearded Anole). MAXIMUM ELEVATION.** *Anolis guamuhaya* is distributed in Sierra de Trinidad and is apparently confined to the Guamuhaya massif, south of Sancti Spiritus, central Cuba (Garrido et al. 1991. Carib. J. Sci. 27:162–168). This species is found from sea level to

900 m elev. (Garrido et al., *op. cit.*; Henderson and Powell 2009. Natural History of West Indian Reptiles and Amphibians. University Press of Florida, Gainesville, Florida. 496 pp.). Herein we report an elevation record for *A. guamuhaya*. On 8 October 2013 an immature specimen (SVL = 63 mm: MFP 12515: Felipe Poey Natural History Museum, Havana, Cuba) was found basking in secondary vegetation on Pico San Juan (21.98939°N, 80.14956°W; NAD27), Cienfuegos Province, Cuba, at 1015 m elev. This extends the known elevational range by 115 m (Garrido et al., *op. cit.*; Henderson and Powell, *op. cit.*). Pico San Juan, at 1140 m elev., is the maximum elevation in central Cuba.

We thank Julio León, Raimundo López-Silvero, and Leosveli Vasallo for field assistance, and the Cienfuegos Botanical Garden for logistical support.

JAVIER TORRES, Departamento de Biología Animal y Humana, Facultad de Biología, Universidad de la Habana, Cuba (e-mail: javiertorres@fbio.uh.cu); **RUBEN MARRERO**, Instituto de Ecología y Sistemática, La Habana, Cuba; **TOMÁS M. RODRÍGUEZ-CABRERA**, Jardín Botánico de Cienfuegos, Cienfuegos, Cuba.

***ANOLIS LUCIUS* (Cave Anole). MAXIMUM ELEVATION.** *Anolis lucius* is an endemic Cuban lizard with a wide distribution (Rodríguez-Schettino 1999. The Iguanid Lizards of Cuba. University Press of Florida, Gainesville, Florida. 428 pp.) and an elevational range of 0–800 m (Rodríguez et al. 2010. Poeyana 498:11–20). Herein we report a higher elevation for *A. lucius*. On 26 August 2014, a juvenile individual (MFP 12579: Felipe Poey Natural History Museum, Havana, Cuba) was observed at an elevation of 1080 m, exceeding the previous record by 280 m. The specimen was found at 1030 h sleeping on an upper face of a leaf in a small bush at Pico San Juan (21.988917°N, 80.144556°W; NAD27), Cienfuegos Province, Cuba.

We thank Julio León, Raimundo López-Silvero, and Leosveli Vasallo for field assistance. The management of the Cienfuegos Botanical Garden and the staff of the weather station at Pico San Juan provided for logistical support.

RODRÍGUEZ-CABRERA**, Jardín Botánico de Cienfuegos, Cienfuegos, Cuba (e-mail: tomasmichel.rodriguez@gmail.com); **JAVIER TORRES**, Departamento de Biología Animal y Humana, Facultad de Biología, Universidad de la Habana, La Habana, Cuba (e-mail: javiertorres@fbio.uh.cu).

***APHANIOTUS FUSCA* (Peninsular Earless Agama). ENDOPARASITES.** *Aphaniotus fusca* occurs in southern Thailand southward through Peninsular Malaysia to Sumatra and Borneo (Grismer 2011. Amphibians and Reptiles of the Seribuat Archipelago [Peninsular Malaysia]: A Field Guide. Edition Chimaira, Frankfurt am Main. 239 pp.). To our knowledge there are no published reports of helminths from *A. fusca*. The purpose of this note is to establish the initial helminth list for *A. fusca*.

Twenty-two *A. fusca* from Peninsular Malaysia (mean SVL = 58.5 mm ± 5.6 SD, range = 48–65 mm) deposited in the herpetology collection of La Sierra University (LSUHC), Riverside, California, USA, collected 2002 to 2012 by state: Johor LSUHC 7707, 8120, 8189, 8198, 8209, 9938, 10235; Kedah LSUHC 10307, 10308, 10309; Pehang LSUHC 4853, 4867, 4868, 4869, 4870, 4873, 4883; Perak LSUHC 9192; Selangor LSUHC 4816, 6507; Teregganu LSUHC 8297, 8298 were examined. A lateral incision was made through the body wall and the digestive tract was removed. The esophagus, stomach, small and large intestines were opened longitudinally and searched for helminths utilizing a dissecting microscope. The body cavity was also searched. Helminths were cleared in lactophenol, placed on a microscope slide, coverslipped, and studied using a compound microscope.

Found were three species of Nematoda, four *Cosmocercoides pulcher* (prevalence = number infected/number examined x 100 = 9%; mean intensity = mean number infected lizards = 2.0 ± 1.4 SD, range = 1–2, one *Metetertakis singaporensis* (prevalence = 5%), and one *Orneoascaris sandoshami* (prevalence = 5%). Helminths were deposited in the United States National Parasite Collection, USNPC, Beltsville, Maryland as *Cosmocercoides pulcher* (USNPC 108053), *Meteterakis singaporensis* (USNPC 108054), *Orneoascaris sandoshami* (USNPC 108055).

Cosmocercoides pulcher is widespread in Asian amphibians, and has been reported in two snake species (Baker 1987. Occas. Pap. Mem. Univ. Newfoundland. 325 pp.; Goldberg and Bursey 2002. Comp. Parasitol. 69:162–176; Goldberg et al. 2004. Comp. Parasitol. 71:49–60). *Meteterakis singaporensis* is a common parasite in bufonids in Malaysia (Sandosham 1954. Kuala Liam Malay Inst. 26:210–226), but is also known from *Eutropis multifasciata* also of Malaysia (Singh 1967. Bull. Nat. Mus. Singapore 33:95–100). *Orneoascaris sandoshami* is known from *Megophrys aceras* (Yuen 1963. Parasitology 53:89–94) and *Gonocephalus abbotti* (Goldberg et al. 2005. Herpetol. Rev. 36:450). *Aphaniotus fusca* represents a new host record for *C. pulcher*, *M. singaporensis*, and *O. sandoshami*.

***ASPIDOSCELIS LAREDOENSIS* (Laredo Striped Whiptail). REPRODUCTION AND LIFE HISTORY.** The diploid parthenogenetic whiptail species *Aspidoscelis laredoensis* comprises clonal complexes A and B which are characterized by marked differences in geographic distributions, color patterns, and meristic variation (Walker 1987a. Amer. Midl. Nat. 117:319–332; Walker 1987b. Texas J. Sci. 39:313–334; Walker et al. 1989. J. Herpetol. 23:119–130). In 1984 and 1985, we sought to extend the known distributions of both of these complexes to the northwest from the vicinities of the Texas-Mexico sister cities Laredo-Nuevo Laredo to as many sites as possible both near the Rio Grande and in outlying sites. We searched for Laredo Striped Whiptails using highways in an area over a straight-line distance (SLD) of ~323 km between Laredo (27.542226°N, 99.502707°W, 124 m elev.), Webb Co., and Langtry (29.808987°N, 101.559678°W, 397 m elev.), Val Verde Co., in Texas, and employed a similar search strategy over a SLD of ~263 km at sites between Nuevo Laredo (27.499922°N, 99.502661°W, 110 m elev.), Tamaulipas State, and Lake Amistad (29.471652°N, 101.058606°W, 366 m elev.), Coahuila State, in Mexico (see map in Walker 1987b, *op. cit.*). During these expeditions, we collected the first samples of *A. laredoensis* B, though A was never present (Walker 1987b, *op. cit.*), to the northwest of Laredo-Nuevo Laredo in the Rio Grande Valley at several sites in the sister cities Ciudad Acuña (29.324167°N, 100.931667°W, elev. 271 m), Coahuila-Del Rio (29.327412°N, 100.927104°W, elev. 266 m), Val Verde Co., and Piedras Negras (28.700000°N, 100.523056°W, elev. 250 m), Coahuila-Eagle Pass (28.705480°N, 100.511720°W, elev. 210 m), Maverick Co. Subsequently, reciprocal skin-grafting experiments (Abuhteba et al. 2000. Can. J. Zool. 78:895–904; Abuhteba et al. 2001. Copeia 2001:262–266) revealed that clonal complexes A

and B were mutually histoincompatible indicating their derivation from separate hybridization events between the gonochoristic species *A. gularis* (Texas Spotted Whiptail) x *A. sexlineata* (Six-lined Racerunner). Evidence of the independent evolutionary histories of *A. laredoensis* A and B (Abuhteba et al. 2000, 2001, *op. cit.*) provided the impetus for our recent use of the samples from Ciudad Acuña and Piedras Negras to assess reproductive and life history attributes of *A. laredoensis* B for comparison with data for clonal complex A provided by Paulissen (2000. Herpetol. Nat. Hist. 7:41–57).

We compiled clutch data from dissections and SVL data from measurements of specimens in the samples of *A. laredoensis* B to reconstruct the life history of this clonal complex of lizards in the northwestern-most part of its geographic distribution. GPS data for sites were taken from Google Earth (datum WGS84). The small sample sizes from Del Rio and Eagle Pass precluded their use in the assessment, and visits to these cities since 1995 have revealed apparent extirpation of the species from previously inhabited sites in both cities resulting from urban development. Moreover, increasing tensions along the border since 1995 have precluded return visits to monitor the ecological status of *A. laredoensis* B in Ciudad Acuña and Piedras Negras. We defined the size of sexual maturity in *A. laredoensis* B as 64 mm SVL based on the smallest specimen containing either yolked ovarian follicles or oviductal eggs. We failed to collect juveniles ranging in size from ~32–40 mm SVL prior to the month of July, and so we assume juveniles in this size range collected in July–September were young-of-year (YOY) hatched in June or July. We further classify juveniles collected before July ranging in size from ~45–54 mm SVL as second-year lizards. Means for SVL and clutch size are reported to one decimal place ± 1 SE. A number in parentheses following a datum for either SVL or clutch size represents the number of observations.

We initially collected *A. laredoensis* B on 30 August 1984 in Ciudad Acuña in a sandy riverfront park with large trees interspersed with patches of weedy/grassy vegetation. On that date, we collected five sexually immature YOY (83.3%; 45, 46, 48 [2], 54 mm SVL) and one reproductively quiescent second year lizard (17.7%; 64 mm SVL). We obtained the second sample in Ciudad Acuña, in a tract of mostly mesquite-dominated habitat laid out for a suburban residential development, on 22 May 1985. Included were five lizards (26.3%; 64 [2], 66, 67, 68 mm SVL) with unyolked follicles, two (10.5%; 66, 71 mm SVL) gravid lizards damaged during collection, 11 (57.9%; 64, 66, 68, 69 [2], 70, 71 [3], 72, 75 mm SVL) with yolked ovarian follicles, and one (5.3%; 78 mm SVL) with shelled oviductal eggs. We assumed the five lizards with unyolked follicles would have developed clutches that year. Based on the 12 undamaged gravid females (mean, 70.3 ± 1.08 mm SVL) we observe clutches of two (6), three (5), and four (1) eggs in *A. laredoensis* B, mean 2.6 ± 0.19.

We obtained the third sample of *A. laredoensis* B in Ciudad Acuña, in a different suburban area with scattered clumps of mesquite, on 19 July 1985. Surprisingly, we also obtained one specimen of gonochoristic *A. marmorata* (Marbled Whiptail; UADZ 2024) at this site, the first of this species found in syntopy with either *A. laredoensis* A or B (Walker 1987a, b, *op. cit.*), along with two specimens of gonochoristic *A. gularis* (Texas Spotted Whiptail; UADZ 1349, 1350). Among the eight specimens of *A. laredoensis* B were three YOY (37.5%; 38, 40, 49 mm SVL, mean 42.3 ± 3.38) and five large second and third year females (62.5%; 74, 75, 79, 80, 81 mm SVL, mean 77.8 ± 1.39) with large clutches of four (4) and five (1) eggs, mean 4.2 ± 0.20.

We separately analyzed the collections of *A. laredoensis* B from Piedras Negras at ~78 km SLD southeast of Ciudad Acuña because of significant differences in meristc characters. We first collected lizards in Piedras Negras on 1 September 1984. They were abundant south of the international bridge along foot trails in a swath of waist-high Russian thistle (*Salsola* sp.) between railroad tracks and a highway; but only two reproductively quiescent adults (71, 78 mm SVL) could be obtained from the more than a dozen mostly large adults observed at the site. We obtained the second sample of the species in Piedras Negras, in a shrubby/weedy suburban area, on 23 May 1985. Included were six gravid females (100%; 65 [2], 67, 72, 73, 77 mm SVL mean, 69.8 ± 1.89). Clutch sizes in these females were one (1), two (1), three (2), five (1), seven (1) eggs, mean 3.5 ± 0.25. We collected the third sample of the species in Piedras Negras, at the same site as the second sample, on 20 July 1985. It included four YOY (21.1%; 42, 43 [2], 48 mm SVL, mean 44.0 ± 1.35) and one gravid female (5.3%; 75 mm SVL) damaged during collection. Also present were 11 females with yolked follicles (57.9%; 66, 72 [5], 73, 75 [2], 77, 80 mm SVL) and three with oviductal eggs (15.8%; 70, 71, 72 mm SVL), pooled mean 72.8 ± 0.88. Clutch sizes in these 14 females were two (2), three (5), four (5), five (2) eggs, mean 3.5 ± 0.25.

Analyzed by collecting period, mean clutch size in May and July samples of lizards from Ciudad Acuña ranged from a low of 2.6 ± 0.19 to a high of 4.2 ± 0.20, respectively. Pooling all samples from Ciudad Acuña and Piedras Negras, 37 gravid females had a mean SVL of 72.2 ± 0.72 (64–81) mm and a mean clutch size of 3.30 ± 0.20 (1–7) eggs. The smallest and largest clutch sizes of one and seven were each represented by one lizard. A positive relationship was noted between SVL and clutch size for the pooled sample (adjusted $r^2 = 0.47$, $P \leq 0.0001$).

Using the samples from the two Mexican cities we reconstructed an approximation of the basic life history of *A. laredoensis* B as follows. By late May first clutch production appeared to be well underway in lizards >68 mm SVL and a second clutch could have developed in these lizards in late July. YOY were present in July samples at the same time as development of second clutches in larger lizards and delayed clutches in smaller individuals. YOY seemed to grow to ~50–60 mm SVL before retiring to end the first activity cycle in late October. Based on our sampling, they emerged in late April from winter inactivity to continue growth to reproductive maturity. Only five females (7.9%) >75 mm SVL were present in our pooled sample of 63 specimens. We concluded that the surface activities and data for most individuals of *A. laredoensis* B fit an annual life cycle as outlined by Paulissen 2000 (*op. cit.*) for an array of diploid parthenogenetic *A. laredoensis* clonal complex A situated approximately 445 km to the southeast in Bentsen Rio Grande Valley State Park, Hidalgo Co., Texas (Walker 1987b, *op. cit.*).

Specimens from the collection of the University of Arkansas Department of Zoology (UADZ) and those transferred to the University of Kansas Natural History Museum (KU) included the following: Mexico: Coahuila: Ciudad Acuña, river-front park ESE of international bridge (across Rio Grande from Del Rio, Texas), site CO-5 (30 August 1984 [KU 200090–200095, N = 6]; 22 May 1985 [UADZ 1011, N = 1]); Ciudad Acuña, suburbs WNW of international bridge (across Rio Grande from Del Rio, Texas), site CO-3 (22 May 1985 [UADZ 1012–1030, N = 19]; 19 July 1985 [UADZ 1291, 1292, N = 2)]; Ciudad Acuña, suburbs WNW of international bridge (across Rio Grande from Del Rio, Texas), site CO-4 (19 July 1985 [UADZ 1264–1271, N = 8]); Piedras

Negras, ~5 km S of international bridge between railroad track and highway (across Rio Grande from Eagle Pass, Texas), site CO-10 (1 September 1984 [KU 200096, 200097, N = 2]); Piedras Negras, W of international bridge (across Rio Grande from Eagle Pass, Texas), site CO-9 (23 May 1985 [UADZ 1036–1041, N = 6]; 20 July 1985 [1273–1290, 1 uncatalogued, N = 19]). Specimens were collected under authority of Texas Parks and Wildlife Department Permit No. 61, and permission granted by appropriate officials in Mexico.

***COPHOSAURUS TEXANUS* (Greater Earless Lizard). AQUATIC ESCAPE BEHAVIOR.** Many terrestrial lizard species have been observed attempting to escape potential predators by swimming or submerging underwater, including *Aspidoscelis sexlineatus* (Dillon and Baldauf 1945. Copeia 1945:174; Trauth et al. 1996. Herpetol. Rev. 27:20), *Crotaphytus collaris* (Burt and Hoyle 1934. Trans. Kansas Acad. Sci. 37:193–216), *Scincella lateralis* (Akin and Towsend 1998. Herpetol. Rev. 19:43), *Sceloporus clarkii* (Zylstra and Weise 2010. Herpetol. Rev. 41:86), *Uma exsul* (Estrada-Rodriguez and Leyva-Pacheco 2007. Herpetol. Rev. 38:84–85), and *Gambelia wislizenii* (Medica 2010. Herpetol. Rev. 41:354–355). Herein, we report the escape-to-water behavior of *C. texanus*, a species not previously reported to exhibit this behavior.

On 27 September 2013, while conducting field work at Potrero Grande, Hidalgo, Nuevo León, México (26.008392°N, 100.453522°W, WGS84; 609 m elev.), at 1456 h walking beside a small stream we observed a rapid movement. We observed a juvenile male *C. texanus* (42 mm SVL; 5.9 g) moving quickly over the water, and then stop on a small rock in the middle of the stream (ca. 4–50 cm deep, 1–5 m wide), with numerous rocks forming small islands; the temperature of the water and the rocks was not determined). Several photographs of the lizard were taken (Fig. 1) and then each of us stood on opposite sides of the stream making hand movements and trying to capture it. The lizard crossed the stream on three occasions, stopping several times on the protruding rocks inside the stream, where body parts remained in contact with water. Whenever we tried to approach, it launched from the rock into the water. Eventually the lizard was manually captured, probably due to exhaustion or cooling from contact with the water. Although this behavior may have a high energetic cost due to rapid cooling, it represents an efficient strategy to elude predators. In the water it is well camouflaged and immobile, likely to confuse a potential predator.

Fig. 1. Juvenile *Cophosaurus texanus* resting on a rock in the middle of a stream.

***CYRTODACTYLUS SERIBUATENSIS* (Seribuat Bent-toed Gecko). REPRODUCTION.** *Cyrtodactylus seribuatensis* is known only from islands of the Seribuat Archipelago, Johor State, Peninsular Malaysia (Grismer 2011. Lizards of Peninsular Malaysia, Singapore and their Adjacent Archipelagos. Edition Chimaira, Frankfurt Am Main. 728 pp.). Grismer (*op. cit.*) observed gravid *C. seribuatensis* females carrying two eggs during March, July, and September. In this note we provide additional information on *C. seribuatensis* from a histological examination of museum specimens.

A sample of 39 *C. seribuatensis* consisting of 10 adult males (mean SVL = 59.5 mm ± 9.2 SD, range = 46–72 mm), 16 adult females (mean SVL = 66.2 mm ± 3.2 SD, range = 61–72 mm), 5 subadult females (mean SVL = 48.8 mm ± 6.1 SD, range 41–58, 6 unsexed juveniles (mean SVL = 37.3 mm ± 3.4 SD, range = 33–43 mm; 2 presumably neonates (mean SVL = 26.5 mm ± 3.5 SD, range = 24–29 mm), from islands of the Seribuat Archipelago, Johor State, Peninsular Malaysia collected March 2003, September 2003, July 2004, and deposited in the herpetology collection of LaSierra University (LSUHC), Riverside, California, USA were examined: LSUHC 5191, 5192, 5218, 5221, 5223-5226, 5229, 5522, 5578, 5604, 5778-5780, 5784–5789, 5812, 5813, 6350–6354, 6398, 6413, 6414, 6416–6421, 7516, 7517.

A cut was made in the lower abdominal cavity and the left testis or ovary was removed, embedded in paraffin, cut into 5-μm sections, and stained with Harris hematoxylin followed by eosin counterstain. Enlarged follicles (> 4 mm) or oviductal eggs were counted. Histology slides were deposited in LSUHC.

The only stage noted in the testicular cycle was spermiogenesis in which seminiferous tubules are lined by sperm or clusters of metamorphosing spermatids. Males undergoing spermiogenesis were collected in July (N = 7),

Table 1. Monthly stages in the ovarian cycle of 16 adult female *Cyrtodactylus seribuatensis* from Johor State, Peninsular Malaysia.

Month	N	Quiescent	Early yolk deposition	Enlarged follicles > 4 mm	Oviductal eggs
March	5	4	0	1	0
July	7	4	1	0	2
September	4	2	0	2	0

August (N = 1), September (N = 2). The smallest reproductively active male measured 46 mm SVL (LSUHC 6351) and was collected in July.

Four stages were observed in the ovarian cycle (Table 1): 1) quiescent, no yolk deposition; 2) early yolk deposition, basophilic vitellogenic granules in the ooplasm; 3) enlarged follicles > 4 mm; 4) oviductal eggs. Mean clutch (N = 5) was an invariant 2. The smallest reproductively active female (yolk deposition) measured 61 mm SVL (LSUHC 5225) and was collected in March. There was no evidence that *C. seribuatensis* produces multiple clutches (oviductal eggs and concurrent yolk deposition), although this may reflect our small sample size. While it is clear *C. seribuatensis* exhibits an extended reproductive cycle (Table 1), examination of additional samples will be needed to ascertain if reproduction occurs throughout the year as proposed by Grismer (*op. cit.*).

STEPHEN R. GOLDBERG, Natural History Museum of Los Angeles County, Herpetology Section, Los Angeles, California 90007, USA (e-mail: sgoldberg@whittier.edu); **L. LEE GRISMER,** LaSierra University, Department of Biology, Riverside, California 92515, USA (e-mail: lgrismer@lasierra.edu).

***DIPSOSAURUS DORSALIS* (Desert Iguana). URBAN HABITATS.** The geographical distribution of *Dipsosaurus dorsalis* is thought to include much of the Sonoran Desert in the vicinity of the Phoenix Metropolitan area (Brennan and Holycross 2006. A Field Guide to Amphibians and Reptiles in Arizona, Arizona Game and Fish Department, Phoenix. v + 150 pp.). However, it is absent from virtually all of the Phoenix Mountain Preserves, islands of habitat protected over the last 10–40 years. Sullivan and Flowers (1998. Herpetol. Nat. Hist. 6[1]:13–22) suggested that this absence is due to the lack of Creosote (*Larrea tridentata*) flats in these preserves, which are primarily rocky slope habitat. In this report we document the persistence of *D. dorsalis* along various north to south running xero-riparian corridors in the western Phoenix Metropolitan area, even those with extensive habitat alteration including channelization and adjacent housing developments. We confirm its absence from large expanses of Creosote flats to the northeast of these riparian habitats on the northern edge of the Phoenix region. Our observations are consistent with the view that this lizard reaches the northeastern limit of its distribution in the Phoenix area, and is closely associated with the sandy, open Creosote-dominated microhabitats along intermittent desert streams.

We searched for Desert Iguanas using visual encounter surveys during summer 2014. When patches of appropriate (e.g., presence of at least one Creosote shrub) open habitat were found, one or the other of us undertook 15–30 minute surveys by walking in roughly parallel lines until the patch had been covered completely or time expired. In areas with housing, surveys were conducted by driving slowly (20–45 kph) along streets and scanning the roadway edge, under shrubs and for road-killed lizards; because of the wariness of some (but not all) individual lizards, this method was more efficient than exiting the vehicle and walking along the roadway edge. Lizards seemed especially approachable when surveyors remained in a vehicle. Neighborhoods lacking any sign of remnant habitat were excluded; presence of even occasional Creosote plants among houses (e.g., often at the road edge and along driveway entrances) was deemed sufficient for an area to be recognized as "remnant habitat."

Desert Iguanas were found across a variety of disturbed localities in western Phoenix, but were absent from the far north and northeast areas, even in large preserves. We observed them in vacant lots overgrown with Creosote shrubs, among housing developments of various densities (Fig. 1), and even open lots in which the surface had been scrapped bare of all vegetation (Fig. 2). In some of the latter sites, after scrapping, 1–2 m diameter mounds of soil and rock were deposited around the edges; these small hillocks were subsequently used by the lizards for basking (Fig. 2). Surprisingly, they were absent from relatively undisturbed, open Creosote flats north of New River Dam, Adobe Dam (except for one ~ 1-ha patch 4 km N along the creek bed), and Cave Buttes Dam, dams across the New River, Skunk Creek, and Cave Creek, respectively. These Creosote flats lacking Desert Iguanas are large and apparently little disturbed, except for the ubiquitous presence of grazing-induced changes in vegetation, including increased non-native grasses and invasive shrubs (Fig. 3). It appears that historic riparian corridors now dominated by Creosotes attaining ~1 m in height and lacking Bursage (*Ambrosia deltoidea*) are preferred habitat; most of the flats of the Cave Buttes and Sonoran Preserve sites are numerically dominated by Bursage (Fig. 3).

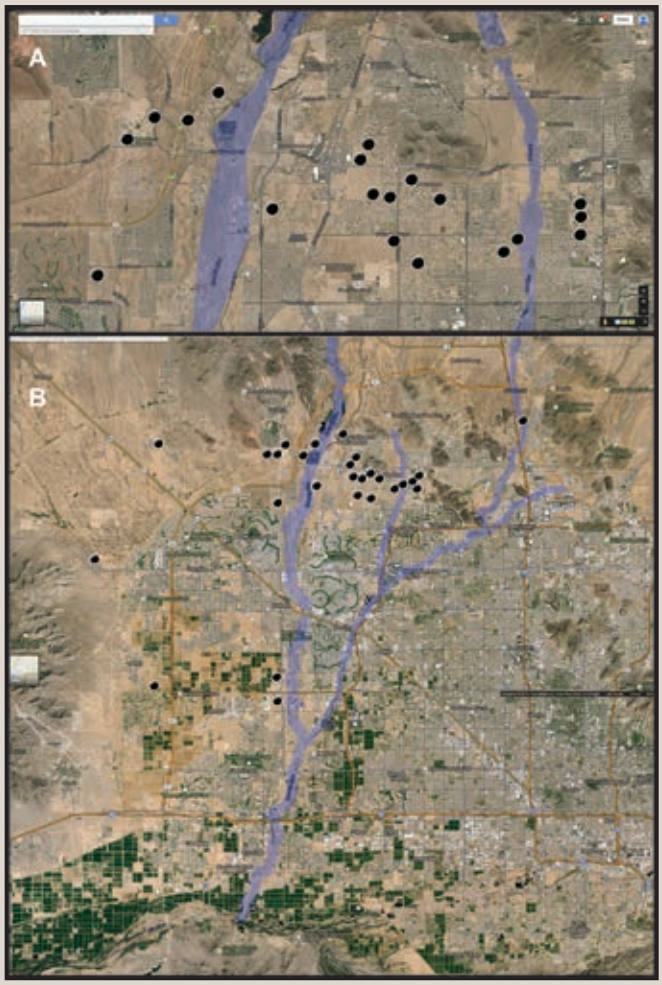

FIG. 1. Satellite image of 14 km x 6 km area of northwest Phoenix showing Desert Iguana localities 12–16 km N of the confluence of the Agua Fria and New rivers (A); note localities between the riparian corridors (shown in blue) among housing developments (center of panel). The entire western Phoenix Metropolitan area with the major xero-riparian corridors highlighted in blue (B). In both panels, Desert Iguana localities (2014 only) are indicated by black circles.

FIG. 2. Desert Iguana on fence in vacant lot (A), northwest Phoenix Metropolitan region. Numerous Desert Iguanas inhabit the adjacent vacant lot with mounds of earth and only a few remnant Creosote shrubs (B) where up to five can be seen basking on the mounds in the mornings. They initially take refuge under Brittlebush and then burrows (center of lower panel).

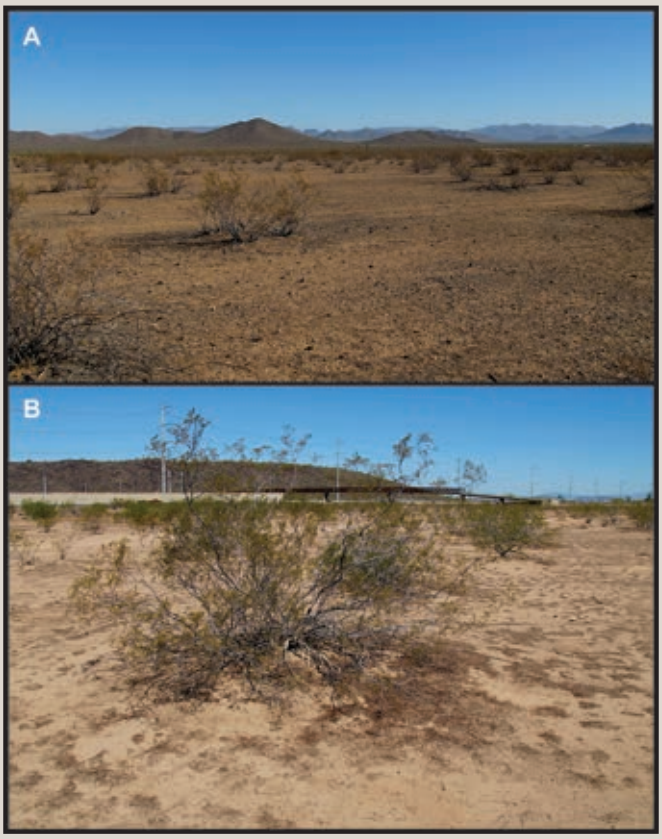

FIG. 3. Intact Creosote flats lacking Desert Iguanas in the Sonoran Preserve near Cave Creek (A). Note the presence of some Bursage but primarily low growing (all < 1 m in height) Creosote on a relatively rocky, gravel substrate. Disturbed (note structures on horizon) habitat with Desert Iguanas along Skunk Creek (B), dominated by relatively large (many > 2.0 m in height) and widely spaced Creosote on a relatively sandier substrate indicative of a xeric riparian corridor.

Overall, Desert Iguanas still occupy remnant habitats in parts of the western Phoenix Metropolitan region, at least in the vicinity of xero-riparian corridors with large, widely-spaced Creosote shrubs and sandy soil with opportunities for burrowing by lizards and presumably rodents (Fig. 1). They persist in low-density housing settings, apparently co-existing with feral cats and a variety of anthropogenic impacts over at least 30 years of direct observation by the senior author (BKS).

We thank Elizabeth, Justin, and Keith Sullivan for assistance in the field. Collecting permits were provided by the Arizona Game and Fish Department (2006–2014, to BKS), and collecting methods were approved as part of IACUC protocols (2006, 2009, and 2011) for surveying and vouchering lizards.

BRIAN K. SULLIVAN (e-mail: bsullivan@asu.edu), and **JAMES M. VERNON**, School of Mathematical and Natural Sciences, P. O. Box 37100, Arizona State University, Phoenix, Arizona 85069, USA (e-mail: jvernon@asu.edu).

***ENYALIUS BILINEATUS* (Two-lined Fathead Anole). COURTSHIP BEHAVIOR.** *Enyalius bilineatus* is a species of semi-arboreal lizard that occurs in the states of Minas Gerais, Rio de Janeiro, Espírito Santo, and the southern states of Brazil (Etheridge 1969. Bull. Br. Mus. [Nat. Hist.] Zool. 18:233–260; Jackson 1978. Arq. Zool. [São Paulo] 30:1–79; Zamprogno et al. 2001. Rev. Bras. Biol. 61:91–94). It is found mainly in Cerrado and Altantic Rainforest biomes of Brazil (Bertolotto et al. 2002. Hereditas 136:51–57). Before this report, the details of *E. bilineatus* courtship behavior were unknown. We observed courtship and copulation behavior in *E. bilineatus* in the Cerrado biome in Minas Gerais, Brazil, under natural conditions. Our observations were made in the Reserva Biológica Unilavras/Boqueirão (21.9998°S, 44.2457°W, WGS84; 1250 m elev.), municipality of Ingaí, Minas Gerais, on 16 November 2006 at 0902 h. We observed, at 4 m distance, one adult male *E. bilineatus* following one adult female. Upon detecting the female, the male slowly positioned himself beside the female. He then quickly climbed on the female and held her in the inguinal region using his forelimbs and jaw (Fig. 1). He then bit her neck and immobilized her hind legs using the fourth digit of his feet, which are well developed in this species. The male

FIG. 1. Courtship behavior and copulation of *Enyalius bilineatus* observed in the Reserva Biológica Unilavras/Boquierão, Brazil.

pressed the hind legs of the female to the ground, preventing her from escaping. Copulation between the individuals involved limited movement of sometimes-intertwined tails. Total time from viewing the male approach the female until leaving the female after copulation was ~21 minutes. After the male left, the female remained in place for another 40 minutes and then disappeared into the vegetation. These same behaviors were observed in *Enyalius perditus* (Lima and Sousa 2006. Rev. Bras. Zoociênc. 8:193–197) under captive conditions.

During pre-mating and mating, the male's color pattern changed within the first five minutes, becoming darker dorsally, a phenomenon also reported in *E. perditus* (Lima and Sousa 2006, *op. cit.*). Such a rapid change in color is likely due to hormonal action, melanophores-stimulating hormone that promotes pigment dispersion (Liem et al. [eds.] 2013. Anatomia Funcional de Vertebrados. Cengage Learning. 560 pp.) and may represent a defense strategy (e.g., crypsis) of *Enyalius* species. During mating individuals remain stationary for a considerable time, and are therefore vulnerable to predators. Our observations demonstrate the occurrence of a similar behavioral pattern for courtship and copulation among species of this genus (Lima and Sousa 2006, *op. cit.*; Migliore et al. 2014. Herpetol. Notes 7:273–276). The reproductive events reported here occurred in November, which coincides with reproductive timing of other species of this genus (Sturaro and Silva 2010. J. Nat. Hist. 44:1225–1238; Migliore et al. 2014, *op. cit.*). Our data corroborate the work of Migliore et al. (2014, *op. cit.*) in finding that the process of courtship and copulation is similar between the natural environment and captivity. This is the first record of courtship behavior and copulation under natural conditions in *E. bilineatus*.

***EULAMPRUS QUOYII* (Eastern Water Skink). PREY COMPETITION WITH BIRD.** *Eulamprus quoyii* is a medium-sized terrestrial diurnal lygosomine skink, widespread in riparian and mesic habitats of the coastal plain, hinterland, and ranges of most of eastern mainland Australia (Cogger 2014. Reptiles and Amphibians of Australia, 7th ed. CSIRO Publishing, Collingwood, Victoria. xxx + 1033 pp.); it is largely arthropodophagous, but occasionally eats smaller lizard species and juvenile conspecifics (pers. obs.). The exotic English House Sparrow, *Passer domesticus*, is common in anthropogenic habitats in eastern Australia; it is largely vegetarian but readily feeds on arthropods especially in the spring-summer breeding period (Frith [ed.] 1982. The Readers' Digest Complete Book of Australian Birds. Readers' Digest Services, Sydney, N.S.W. 615 pp.). This note documents a case of competition between an adult *E. quoyii* and a *P. domesticus* for a spider prey item.

On 13 November 2008, ~1400 h, on a sunny day, T_a = ~26°C, in an urban backyard in Cooranbong, Central Coast region, New South Wales, Australia, (33.08°S, 151.45°E, WGS84; 12 m elev.), where *E. quoyii* is common, the first author (TJA) from within the house through double glass sliding doors observed a male *P. domesticus* (total length ~150 mm) alight on the concrete paving outside and peck at a spider, which jumped away. The spider was most likely a White-banded Jumping Spider (*Hypoblemum albovittatum*: Salticidae), a medium-sized (cephalothorax + abdomen length ~8 mm) species that is the most common salticid at this locality, although the Wattle Jumping Spider (*Sandalodes scopifer*), the Biting Jumping Spider (*Opisthoncus mordax*), and an undescribed species have also been recorded (TJA, pers. obs.). Within seconds of the first peck an adult (total length ~280 mm, SVL ~100 mm) *E. quoyii* raced out from under a nearby flowerpot and also chased the rapidly jumping spider. Both aspiring predators pursued the leaping spider for ~15–20 seconds and each made several, perhaps half a dozen, unsuccessful attempts to seize it. The *E. quoyii* apparently ignored the close proximity and near-miss pecks of the *P. domesticus*, which in turn appeared unconcerned by the close proximity of the *E. quoyii* and its rapid movements. The contest concluded when the *E. quoyii* successfully captured the spider, and ran off, briefly stopping to swallow, while the *P. domesticus* flew back to the roof from whence it had come. *Eulamprus quoyii* may become tolerant to the close proximity of humans where they are not persecuted, but are very wary of local bird predators such as Kookaburras (*Dacelo gigas*) and Pied Butcher Birds (*Cracticus nigrogularis*) (TJA, pers. obs). The above observation provided evidence that exotic *P. domesticus* will directly compete with endemic lizards for arthropod prey; it was also notable that the *E. quoyii* apparently did not perceive the relatively large-bodied *P. domesticus* as a threat despite its sharp and strong beak.

***LERISTA ARENICOLA* (Bight Slider). VIVIPARITY.** Viviparity has evolved in many vertebrate lineages, but shows the greatest diversity in squamate reptiles, where it has evolved over 100 times (Blackburn 2000. Comp. Biochem. Physiol. A 127:391–409). The transition from oviparity to viviparity is often attributed to the adaptive benefit provided to offspring in cooler environments (Shine 1983. Oecologia 57:397–405). The

TABLE 1. Maternal reproductive and offspring traits for two viviparous semi-fossorial skinks, *Lerista arenicola*.

ID number	Parturition date	Maternal post-partum mass (g)	Offspring number	Offspring mass (g)	Clutch mass (g)
1	9–12 Feb 2007	3.3432	1	0.2826	1.0702
			2	0.2514	
			3	0.2742	
			4	0.2620	
2	5–8 Feb 2007	2.5134	1	0.3054	0.5984
			2	0.2939	

family Scincidae is the largest and most diverse group of lizards globally (Rabosky et al. 2007. Proc. Royal Soc. B 274:2915–2923), and contains both egg-laying (oviparous) and live-bearing (viviparous) species. In Australia, the semi-fossorial scincid genus *Lerista* is the second most diverse lineage of skinks, and ranges from fully limbed semi-fossorial to limbless burrowing species (Skinner et al. 2008. BMC Evol. Biol. 8:310–318). The majority of *Lerista* species are oviparous, with viviparity known only from two southern species: *L. microtis* and two populations of *L. bougainvillii* (Qualls et al. 1995. J. Zool. 237:13–26). However, data on the reproductive mode of other *Lerista* species is insufficient to confirm these as the only cases of viviparity within the genus. Herein, we report the occurrence of viviparity in an additional *Lerista* species from southern mainland Australia.

Two adult female *L. arenicola* were collected from Talia Caves and Venus Bay, South Australia (33.329444°S, 134.800278°E, WGS84; 34 m elev.) on 11 November 2006, and returned alive to the Museum of South Australia. In the museum, both lizards were housed together in a glass aquarium (60L x 35W x 45H cm) with an 8-cm layer of loose sand and dirt with a bark shelter; a 60-watt heat lamp produced a thermal gradient (21–35°C). Lizards were fed small crickets three times weekly, and water was always available. Lizards were checked daily for evidence of eggs or offspring. In early February 2007, each of the two females produced a litter of live offspring. See Table 1 for details on dates of parturition, maternal traits, and offspring traits. While we lack precise data on the duration of embryogenesis in *L. arenicola*, it is clear that both skinks were gravid upon arrival in the lab. The period of gestation within the laboratory was 85 and 81 days for female 1 and 2, respectively. This interval, while a rough indication, is similar for other semi-fossorial *Lerista* species, which ovulate in late summer and produce a single clutch per year (Qualls and Shine 1998. J. Evol. Biol. 11:63–78).

Viviparity in *L. arenicola* supports the "cool climate" hypothesis in occurring more frequently in species from colder climates. Previous work comparing the climate of mainland and island populations of *L. bougainvillii* and populations of *L. microtis*, indicate that these viviparous populations occupy cooler environments than their oviparous relatives, being found predominantly on cool southern islands (Qualls et al. 1995, *op. cit.*). Similar to the other two viviparous species, *L. arenicola* is restricted to leaf-litter microhabitats on pale coastal sands along the Great Australian Bight in southeastern, western, and southwestern South Australia. In the eastern part of its range, *L. arenicola* overlaps with the distribution of *L. microtis*, where it presumably experiences similar environmental conditions and selective forces.

The molecular phylogeny for *Lerista* indicates that *L. bougainvillii* and *L. microtis* occupy two separate clades, and thus represent independent evolutionary origins of viviparity (Skinner et al. 2008, *op. cit.*). However, as *L. microtis* and *L. arenicola* are sister species, it is probable that viviparity in both species may represent a single evolutionary event. The presence of viviparity in *L. arenicola* and within two distinct populations of *L. bougainvillii* (Fairburn et al. 1998. Mol. Phylo. Evol. 10:95–103), suggests the evolution of viviparity and its maintenance may occur readily within members of the genus *Lerista*.

CAROLYN KOVACH, South Australian Museum, Adelaide, South Australia, Australia, (e-mail: Carolyn.Kovach@samuseum.sa.gov.au); **BRETT A. GOODMAN**, School of Earth & Environmental Science, University of Adelaide, Adelaide, South Australia, 5005, Australia.

***PHYMATURUS PALLUMA* (High Mountain Lizard). COPROPHAGY.** *Phymaturus palluma* is a medium-sized, saxicolous, herbivorous, and viviparous lizard that inhabits the Altoandina phytogeographic province in the Andes Highlands, Argentina. During the summer 2014 I observed juveniles of *P. palluma* eating small bites of fecal pellets at the Aconcagua Provincial Park, Mendoza, Argentina (32.8453°S, 69.7619°W, WGS84; 2480 m elev.). After recording this behavior, I approached to get a closer view, and I saw that the feces, based on size, were of adult individuals of this species. This is the first record of coprophagy in *Phymaturus* lizards.

This behavior was reported in the herbivorous lizards *Sauromalus obesus* and *Iguana iguana* (Montanucci 1999. Herpetol. Rev. 30[4]:221–222; Troyer 1982. Science 216:540–542), which shows an association of hatchlings with adults of the same species similar to *P. palluma*. It has been demonstrated that coprophagy in *I. iguana* is related to the transfer of anaerobic gut symbiotic microbes that are utilized for effective degradation of plant materials. Possession of more complex microflora was associated with improved growth rate and digestive efficiency (Troyer 1982, *op. cit.*). Symbiotic microbes of *P. palluma* have not been studied. *Phymaturus palluma* shows social behaviors between juveniles and adults (Videla 1982. Bol. Mus. Cienc. Nat. Antropol. 3:57–62), similar to those in other lizards where transfer of microflora occurs; therefore, transfers of symbiotic microflora from parents to offspring via coprophagy might be possible.

NADIA VICENZI, IADIZA-CCT Mendoza, CONICET, Mendoza, Argentina; e-mail: nvicenzi@mendoza-conicet.gob.ar.

***PLESTIODON CALLICEPHALUS* (Mountain Skink). REPRODUCTION.** *Plestiodon callicephalus* is known from southeastern Arizona and southwestern New Mexico in the United States, and Sonora, Chihuahua, Sinaloa, south to Nayarit and Jalisco in Mexico (Swann et al. 2009. *In* Jones and Lovich [eds.], Lizards of the American Southwest, pp. 446–448. Rio Nuevo Publ., Tucson, Arizona). Anecdotal information on reproduction exists for this species including clutches of three to six eggs, female guarding of the eggs, and hatchlings measuring 20–25 mm (Swann et al. 2009, *op. cit.*). There is a report that *P. callicephalus* (as *Eumeces*) is viviparous (Taylor 1985. Herpetol. Rev. 16:27). The purpose of this note is to add information on the reproductive cycle of *P. callicephalus*.

A sample of 14 *P. callicephalus* consisting of four males (mean SVL = 57.8 mm ± 8.2 SD, range = 48–68 mm), five females (mean SVL = 64.0 mm ± 5.5 SD, range = 57–68 mm), and five juveniles (mean SVL = 29.4 mm ± 3.8 SD, range = 25–35 mm) were examined

FIG. 1. Gravid *Plestiodon callicephalis* (LACM 99505) collected June 1959 from Nayarit, Mexico. Arrow is on embryo in oviductal egg.

from the herpetology collection of the Natural History Museum of Los Angeles County (LACM), Los Angeles, California. Lizards were collected 1949 to 1966 from the following sites: Mexico: Nayarit LACM 99503–99508; Sinaloa LACM 6768, 6769, 6770; Sonora LACM 99513, 99514; United States: Arizona, Cochise County LACM 99501; Santa Cruz County LACM 5929, 99502.

A cut was made in the lower abdominal cavity and the left testis or ovary was removed, embedded in paraffin, cut into 5-μm sections and stained with hematoxylin followed by eosin counterstain. Oviductal eggs were counted. Histology slides were deposited at LACM.

Two stages were noted in the testicular cycle: 1) regressed, seminiferous tubules are reduced in size and contain spermatogonia and interspersed Sertoli cells; 2) spermiogenesis, seminiferous tubules are lined by clusters of sperm or metamorphosing spermatids. Two males from April were undergoing spermiogenesis, SVL = 48, 58 mm. One male each from June and July, SVL = 68, 57 mm, respectively, contained regressed testes. Two stages were observed in the ovarian cycle: 1) quiescent, no yolk deposition; 2) oviductal eggs with embryos. One female from June, SVL = 68 mm and three from July, respectively, SVL = 57, 59, 68, contained quiescent ovaries. One female from June contained nine oviductal eggs with embryos (Fig. 1). Five subadults were from August. The smallest, SVL = 25 mm is within the range of neonates in Swann et al. (*op. cit.*).

Plestiodon callicephalus reproduces during the Spring as do numerous other North American skinks (for examples see Goldberg 2005. Texas J. Sci. 57:295–301). Nine is a new maximum litter size for *P. callicephalus*. My observations of embryos in LACM 99505 confirm the observation of Taylor (*op. cit.*) that *P. callicephalus* is viviparous. Whether *P. callicephalus* is both oviparous (Swann et. al., *op. cit.*) and viviparous (Taylor, *op. cit.*; this report) will require further study.

I thank Greg Pauly (LACM) for permission to examine *P. callicephalus* and Richard Feeney (LACM) for figure preparation.

STEPHEN R. GOLDBERG, Whittier College, Department of Biology, Whittier, California 90608, USA; e-mail: sgoldberg@whittier.edu.

***PLESTIODON GILBERTI* (Gilbert's Skink). MALE COMBAT.** *Plestiodon gilberti* is not known to be territorial (Lemm 2009. *In* Jones and Lovich [eds.], Lizards of the American Southwest, pp. 449–451. Rio Nuevo Press, Tucson, Arizona) and we are not aware of any reports of intraspecific combat or aggression in this species (e.g., Jones 1985. Cat. Amer. Amphib. Rept. 372:1–3), although male aggression is well known in other species in the genus (Cooper and Vitt 1987. Herpetologica 43:7–14). On 21 April 2014 at approximately 1005 h, HDD observed two adult male *P. gilberti* (both approximately 90 mm SVL) on the ground in a *Prosopis glandulosa*, *Populus fremontii*, and *Salix* sp. riparian woodland at Big Morongo Canyon Preserve, 1.2 km E of Morongo Valley, San Bernardino Co., California, USA (34.049837°N, 116.567869°W, WGS84; 765 m elev.). One individual was laying roughly perpendicular to the other and had the other lizard's head grasped in its mouth. Upon approach, the two lizards split up and quickly disappeared into the leaf litter and other debris on the forest floor. Although only one of the lizards was photographed (UAZ 57612-PSV, verified by G. Bradley) and is readily identifiable as a male in breeding colors, the second lizard was very similar to the first with respect to size, proportions, and head coloration and thus we are confident that it was also a male.

HENRY D. DETWILER, Southwest Birders, 8815 S. Ave D, Yuma, Arizona, 85364, USA (e-mail: henrydetwiler@earthlink.net); **JAMES C. RORABAUGH**, P.O. Box 31, Saint David, Arizona 85630, USA (e-mail: jrorabaugh@hotmail.com).

***SCELOPORUS CONSOBRINUS* (Prairie Lizard). MORTALITY.** Discarded bottles have been well documented as fatal traps for small mammals, but few accounts report on other small vertebrates becoming trapped inside such bottles (Morris and Harper 1965. Proc. Zool. Soc. Lond. 145:148–153; Pagels and French 1987. Am. Midl. Nat. 118:217–219; Benedict and Billeter 2004. Southeast. Nat. 3:371–377). Glass bottles inclined with openings pointed uphill >15° render escape almost impossible for small vertebrates and other organisms, as they cannot climb the slippery sides or provide momentum to move bottles (Morris and Harper 1965, *op. cit.*; Gerard and Feldhamer 1990. Am. Midl. Nat. 124:191–194; Benedict and Billeter 2004, *op. cit.*).

On 22 May 2012, we collected a clear glass beer bottle containing a dead *Sceloporus consobrinus* (Fig. 1) in south-central Nebraska, USA, 13.4 km N and 4.9 km E of Smithfield in Gosper Co. (40.6921°N, 99.6821°W; WGS84). The littered bottle was discovered on a grassy slope with scattered trees adjacent to rolling grasslands near an irrigation canal spillway ("Johnson Return to River") on the Central Nebraska Public Power and Irrigation District's supply canal located downstream of the

FIG. 1. A fatally trapped *Sceloporus consobrinus* discovered in a littered glass bottle in south-central Nebraska.

Canaday Steam Plant. The opening of the glass bottle was pointed upward on the slope, and it also contained a single carrion beetle. The lizard was deposited in the natural history collections at the Sternberg Museum of Natural History, Fort Hays State University, Hays, Kansas (FHSM 16552) and verified by Curtis J. Schmidt. To our knowledge this represents the first report of this species trapped in littered debris.

Other reports have described herpetofaunal mortalities associated with littered bottles and cans (Herrington 1985. Herpetol. Rev. 16:113). At least 33 lizards and plethodontid salamanders were reported fatally trapped in littered bottles in the eastern United States, but numbers likely underrepresented actual fatalities of individuals due to decomposition and scavenging (Benedict and Billeter 2004, *op. cit.*). Moreover, remains of 140 Insular Lizards *(Podarcis hispanica atrata*) were observed in discarded bottles and tin cans at dumps in islands off the coast of Spain (Castilla and Bauwens 1991. Biol. Conserv. 58:69–84). As suggested for shrews, small reptiles and amphibians potentially are entering bottles to feed upon trapped insects and other invertebrates (Morris and Harper 1965, *op. cit.*; Gerard and Feldhamer 1990, *op. cit.*).

***SCELOPORUS UNIFORMIS* (Yellow-backed Spiny Lizard). TAIL REGENERATION.** We report on *Sceloporus uniformis* having two regenerated sections along its tail from an individual captured near the lower Virgin River in Beaver Dam, Mohave Co., Arizona, USA (36.8983°N, 113.9222°W). Similar to many species of lizards, spiny lizards (*Sceloporus* spp.) can regenerate autotomized tails. Intravertebral fracture planes cross each vertebrae, allowing for tail autotomy and regeneration to occur from point of amputation (Jamison 1964. Herpetologica 20:145–149). The regenerated section of an autotomized tail has calcified cartilaginous tubes lacking the intravertebral autotomy fracture planes (Bateman and Fleming 2009. J. Zool. 277:1–14). This would suggest that regenerated tails should not be able to regenerate a second time because of the loss of the specialized fracture planes found in bony vertebrae. However, Alibardi (2014. Prog. Histochem. Cyto. 48:143–244) suggested that lizards with autotomous fracture planes are able to regenerate their tails outside of the fracture planes. Compared to lizard species with non-autotomous planes, Alibardi (2014, *op. cit.*) suggests that species with fracture planes can have a new regeneration of a regenerated tail because stem cells are present in the connective tissue containing fibroblasts in the tail. Despite the histological evidence, there are few examples of lizards with two regenerated sections of their tails and, we believe, this is the first documentation of two regenerated sections in a single tail for *S. uniformis*.

We captured *S. uniformis* in trap arrays established in riparian habitat with cottonwood (*Populus fremontii*), willow (*Salix* spp.), and saltcedar (*Tamarix* sp.) trees as part of a larger project to examine the effects of saltcedar biocontrol and restoration on herpetofaunal communities (Bateman et al. 2014. Biol. Invasions DOI:10.1007/s10530-014-0707-0). On 26 May 2014, we captured a male *S. uniformis* that weighed 44 g, had a snout–vent length of 109 mm, and tail length of 79 mm. The tail was regenerated at two locations with the first regenerated section beginning at 23 mm from the vent and the second section beginning at 61 mm from the vent (each section was 38 mm and 18 mm in length, respectively) (Fig. 1).

FIG. 1. Ventral (A) and dorsal (B) view of *Sceloporus uniformis* having two regenerated sections along its tail, Beaver Dam, Arizona

***VARANUS PANOPTES* (Yellow-spotted Monitor). DIET AND FORAGING BEHAVIOR.** Although large predatory animals are capable of capturing and consuming large prey, most regularly consume smaller prey (e.g., Hart and Hamrin 1990. *In* Hughes [ed.], Behavioural Mechanisms of Food Selection, pp. 235–253. Springer-Verlag, Berlin). Large monitor lizards are no exception. For example, *Varanus bengalensis* reaches 1.75 m in total length but 75% of its diet consists of small invertebrates (Auffenberg 1994. The Bengal Monitor. The University Press of Florida, Gainesville. 560 pp.). Generalist predators such as large monitor lizards use different foraging strategies to obtain different prey, a pattern well documented for *V. bengalensis* (Auffenberg 1994, *op. cit.*). One foraging behavior noted was regular searches for dung beetles (Scarabaeidae) in the dung pats of (mainly) large mammals. Herein we document similar foraging behavior

in the Yellow-spotted Monitor, *Varanus panoptes*, in northern Australia.

The Yellow-spotted Monitor is a large lizard (up to 1.5 m in total length) inhabiting riparian areas and floodplains in tropical Australia (Cogger 2000. Reptiles and Amphibians of Australia. Reed New Holland, Sydney. 808 pp.). It is a generalist carnivore consuming mammals, frogs, reptiles, fish, invertebrates, and the eggs of reptiles and birds (Christian 2004. *In* Pianka and King [eds.], Varanoid Lizards of the World, pp. 423–429. Indiana University Press, Bloomington and Indianapolis. 588 pp.). Invertebrates eaten include orthopterans, ants, lepidopterans, spiders, centipedes, roaches, hemipterans, beetles, trichopterans, and crabs (Christian 2004, *op. cit.*). Studies of *V. panoptes* diet are based mainly on dissections of museum specimens, and on stomach flushing of live individuals, although a few observations of feeding and prey capture have recently been published (Shannon 2008. Biawak 2:80–86; Shannon and Mendyk 2009. Biawak 3:85–87; Rhind and Doody 2011. Herpetofauna 41:64–65; Doody et al. 2012a. Herpetol. Rev. 43:339–340; Doody et al. 2012b. Herpetol. Rev. 43:491–492; Rhind et al. 2013. Herpetol. Rev. 44:516–517; Rhind et al. 2014. Herpetol. Rev. 45:335–336). Collectively, these studies and observations indicate that *V. panoptes* is capable of a wide range of foraging behaviors including capturing fast prey, subduing large prey, excavating inactive or hidden prey including eggs, foraging for aquatic prey, raiding poultry pens, and scavenging roadkill and human consumable waste.

At 0935 h on 9 July 2010 we observed, photographed, and videoed a large male *V. panoptes* tearing apart a cattle dung pat on the campground at El Questro Station, El Questro Wilderness Park, in the Kimberley Region of Western Australia (16.006297°N, 127.979819°E) (http://dx.doi.org/10.6084/m9.figshare.1281287). Upon closer examination (within 3 m) we observed the lizard to: 1) tongue-flick in and around the pat; 2) tear apart the pat with alternating forelimbs; 3) press its nose into the pat; and 4) capture small prey items and swallow them. Although we could not confirm it with absolute certainty, the prey items appeared to be dung beetles, which we later found to be relatively common in other dung pats in the area (there were no other similar-sized invertebrates in the 10 pats we examined). After the lizard tore apart the pat, it proceeded in a straight line to another pat 7 m away. In this way the lizard tore apart seven dung pats in a ~30-minute period. The pats were all within a 50-m^2 area. The dung pats were from cattle, which invade the campground to forage on green grass late in the dry season. The campground is encompassed by the Station, a million-acre property that supports ~5000 head of cattle (M. Bass, pers. comm.).

Varanus bengalensis forages for dung beetles in the dung pats of cattle, elephants, rhinoceros, donkeys, camels, blackbuck, nilgai, horses, and canids (Auffenberg 1994, *op. cit.*). In particular, *V. bengalensis* regularly visited bovine dunging sites, which contained a rich and diverse abundance of dung beetles. The lizards also demonstrated spatial memory, visiting but not disturbing fresh dung pats which have few beetles, then revisiting the pats days later when beetle densities were higher. We do not know if the *V. panoptes* knew of the dung pats previously; however, the lizard clearly focused on dung pats exclusively during the feeding bout. Earlier in the year when dung pats are not available at the site, we commonly observe *V. panoptes* foraging in the campground on mowed grass for buried prey including beetle larvae, hymenopteran larvae, and frogs. They also occasionally scavenge on human food items. Other producers of significant amounts of dung in the east Kimberley are feral donkeys, horses, cattle, and pigs. Dung foraging in monitors may be a relic; historically, prominent megafauna would have provided an abundance of dung pats and beetles for ancestral species of large monitors. Auffenberg (1994, *op. cit.*) estimated that the habit of gleaning dung beetles from Bovine pats by Asian monitors extended back into the Pliocene, based on fossil evidence from the Varanidae, Bovidae, and Scarabaeidae.

The great breadth of both food types and foraging strategies in *V. panoptes* probably increases the likelihood of individual variation of both. Individual variation in prey preference may be critical for the viability of *V. panoptes* populations in the Kimberley Region as they face the invading Cane Toad (*Rhinella marina*). *Varanus panoptes* is one of three species of monitor lizards that suffers severe population-level declines, via lethal toxic ingestion, with the invasion of Cane Toads (e.g., 83–96%, Doody et al. 2009. Anim. Conserv. 12:46–53). Toads have since invaded El Questro in 2012–2013. Perhaps individuals that prefer non-frog prey such as invertebrates will comprise the proportion of animals surviving the toad invasion.

J. SEAN DOODY, Department of Ecology and Evolutionary Biology, University of Tennessee, 569 Dabney Hall, Knoxville, Tennessee 37996-1610, USA (e-mail: jseandoody@gmail.com); **GRAEME SAWYER**, 19 Tasman Circuit, Wagaman, Northern Territory 0810, Australia (e-mail: graemes@entity1.com); **KIM HANDS**, Stop the Toad Foundation, 2 Delhi Street, West Perth, Western Australia 6005, Australia (e-mail: kim@stopthetoad.org.au).

***VARANUS PANOPTES* (Yellow-spotted Monitor). TOXIC PREY AVOIDANCE.** It is well established that toxic Cane Toads (*Rhinella marina*) poison some predator species attempting to ingest them (Lever 2001. Cane Toad: The History and Ecology of a Successful Colonist. Westbury, Yorkshire). In a few species this interaction translates into strong, population-level impacts; for example, *Varanus panoptes* suffers population declines of about 90% upon toad arrival (Doody et al. 2009. Anim. Conserv. 12:46–53; Ujvari and Madsen 2009. Herpetol. Conserv. Biol. 4:248–251). However, it is not known whether the surviving ~10% possessed genetic-based immunity (Ujvari et al. 2013. Evolution 67:289–294), an innate adaptive avoidance of frogs, or whether non-lethal encounters result in lizards learning to avoid Cane Toads (Llewelyn et al. 2013. Austral. Ecol. 39:190–197). Behavioral observations, while insufficient alone to allow distinguishing among those hypotheses, can clarify interactions that can facilitate choosing which hypothesis is the best to pursue. While studying the nesting biology of *V. panoptes* in the Kimberley region of tropical Australia, we captured video of a natural interaction between a *V. panoptes* and a Cane Toad, soon after the arrival of toads to the site.

In April and May 2013 we monitored four *V. panoptes* nesting warrens for female activity using Moutrie I-35® remote game cameras at El Questro Wilderness Park, Western Australia (15.895033°S, 128.132456°E). The site is mainly woodland savannah and is in the wet-dry tropics; the nesting warrens were in the sandhill of a riparian area. Cameras were placed on the trunks of small trees near the burrow entrances of warrens. Two of the cameras were set to take still photographs and two set to take short videos with an associated photograph (30 sec in duration). At 0829 h on 1 May a video captured the interaction of an adult gravid female *V. panoptes* and an adult Cane Toad (http://dx.doi.org/10.6084/m9.figshare.1281314). The video begins by showing the lizard with its head turned towards the toad, which was sitting in shade next to a burrow opening (Fig. 1). The direction of her gaze and repeated tongue-flicking (6 flicks in that posture for 10

FIG. 1. Game camera photograph of a gravid female *Varanus panoptes* near the entrance of her nesting burrow, looking towards a Cane Toad (*Rhinella marina*) that is sitting at the base of a small tree (in shadow). The dust in the air is a result of the lizard's digging action just before the photograph was taken.

seconds), suggested that she was aware of the toad's presence. At 11 seconds the lizard turned away from the toad and burrow entrance, at which time the toad hopped quickly into the burrow, possibly in response to the lizard's movement. The lizard walked slowly about 0.5 m away from the burrow, during which time she flicked her tongue nine times; at 24 seconds the lizard ceased tongue-flicking and flattened out her body and basked in a patch of sunlight for the last 6 seconds of the video. Toads had arrived at the site during the previous wet season, sometime between November 2012 and March 2013. When we excavated the warrens in May and June most of the burrows contained 1–4 adult toads. Over the next few weeks the lizard completed her nesting in the same burrow, and was seen several times during this process, indicating that she was not a victim of toad poisoning. Excavation of her burrow revealed her eggs but no more toads.

As far as we know, this is the first direct observation of the interaction between a *V. panoptes* and a Cane Toad in nature (but see Llewelyn et al. 2013, *op. cit.*, for field experiments in which *V. panoptes* were offered toads from a noose). The lizard, which was clearly large enough to consume the toad, was not toad-naïve, but may not have experienced toad toxin. It is possible that the lizard was satiated, or that *V. panoptes* do not feed while gravid, or during the nesting process. However, it is equally likely that the lizard avoided the toad due to either innate avoidance or a learned response to toad poisoning. Further monitoring of *V. panoptes* nesting warrens as toads arrive could reveal insightful interactions that clarify the behavioral repertoire of *V. panoptes* for dealing with Cane Toads. These interactions could help disentangle competing hypotheses underpinning the surviving 10% of *V. panoptes* during the Cane Toad invasion.

***WOODWORTHIA MACULATA* (Common Gecko). LEUCISM.** Leucism is a condition where the lack of deposition of melanin in the skin results in a white or pale coloration of the animal, but the eyes maintain normal pigmentation (cf. albinism; Bechtel 1995. Reptile and Amphibian Variants: Colors, Patterns, and Scales. Krieger Publishing Co., Malabar, Florida. 206 pp.). Leucism can vary from partial (<25%, also defined as piebaldism) to completely white individuals (van Grouw 2006. Dutch Birding 28:79–89; Rocha and Rebelo 2010. Herpetol. Notes 3:361–362). Occurrence of leucistic New Zealand geckos in the wild are uncommon (T. Jewell, pers. comm.) and the few observations are generally not recorded.

On 25 February 2014, several *Woodworthia maculata* were caught at dusk, under a pile of rocks close to the shoreline at an island in Whakatane, New Zealand. One of the three individuals was an adult female (SVL = 67 mm) with very pale white

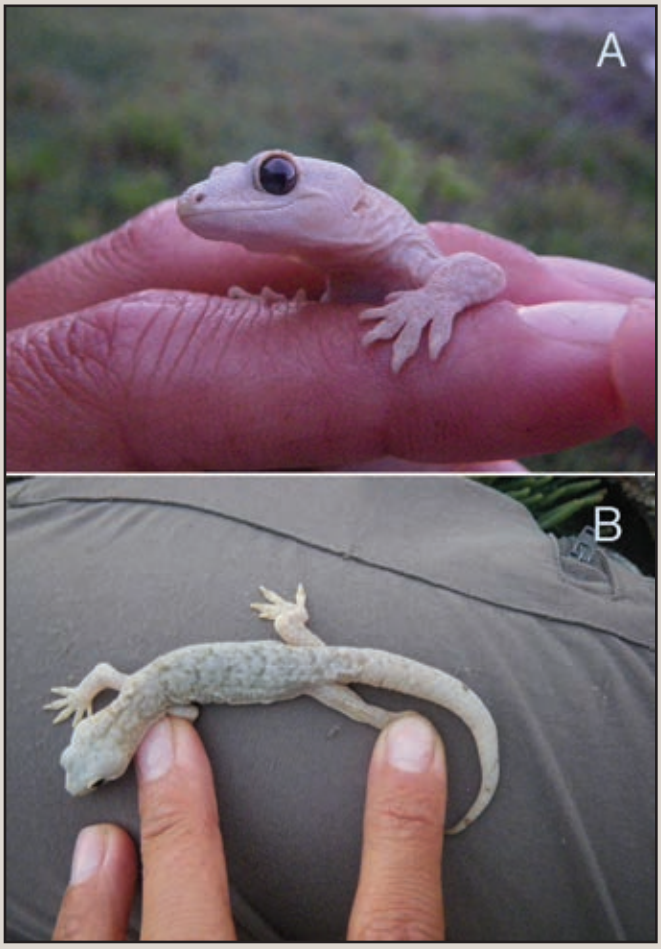

FIG. 1. Leucistic female *Woodworthia maculata*, (A) lateral head showing the pigmented eyes, and (B) light patterning on the dorsal region.

coloration and dark viscera visible through the translucent skin. The eyes were pigmented, indicating that the individual was not an albino (Fig. 1A). The female also had light brown patterns on its dorsal region (Fig. 1B). This nocturnal species is generally grey, brown or olive-green in color with highly variable dorsal patterning, and has a large geographical range in New Zealand (Jewell 2008. Reptiles and Amphibians of New Zealand. New Holland, New Zealand. 143 pp.). This is one of the rare observations of leucism occurring in wild populations of *W. maculata*.

MARLEN BALING, Institute of Natural and Mathematical Sciences, Massey University (Albany Campus), Private Bag 102904, Auckland 0745, New Zealand; e-mail: m.baling@gmail.com.

***XANTUSIA GRACILIS* (Sandstone Night Lizard). DIET AND FORAGING BEHAVIOR.** Occurrence of *Xantusia gracilis* is limited to a small range of sandstone habitat in the Anza-Borrego Desert of southern California. Due to the location and cryptic nature of *X. gracilis*, very little information has been gathered on its natural history. In captivity, these lizards have been observed eating the eggs of *Phyllodactytus nocticolus* (as *P. xanti*) (Grismer and Galvan 1986. Trans. San Diego Soc. Nat. Hist. 21:155–165). While the diet of *X. henshawi* has been extensively examined through the analysis of stomach contents (Brattstrom 1952. Copeia 1952[3]:168–172), to my knowledge, the hunting behavior and prey items of *X. gracilis* have never been observed in the wild.

FIG. 1. *Xantusia gracilis* with beetle immediately before predation.

FIG. 2. *Xantusia gracilis* showing interest in *Trimerotropis pallidipennis*.

On 25 May 2014, we observed an adult *X. gracilis* exposed on a sandstone wall. Light was immediately taken off of the animal in an effort to prevent it from retreating. By the time I readied my camera for a photo voucher, the lizard had disappeared. I approached the last known location of the lizard and discovered it inside the crevice of an exfoliating slab of sandstone. While attempting to take a photo of the lizard through the opening, it exited and consumed an insect on the artificially illuminated sandstone surface. It quickly retreated to the crevice where it was witnessed masticating, and licking its eye. It was observed for about an hour, emerging to prey on various insects, followed by partial to full retreat to the crevice soon after each catch or miss. One of the insects consumed was identifiable as a small beetle (Coleoptera) (Fig. 1). At least one potential prey item was rejected after approach and inspection by the lizard. Interest was shown in a *Trimerotropis pallidipennis* (Pallid-winged Grasshopper) (Fig. 2), with the lizard making a sudden movement in response to the grasshopper leaping. It was difficult to distinguish whether this was a predatory strike or the lizard startled from the grasshopper movement. No physical contact was made with the lizard and it did not appear to be disturbed by human presence or artificial lights. All of the mentioned behavior was video recorded and can be viewed by request to the first author.

SQUAMATA — SNAKES

***AGKISTRODON CONTORTRIX* (Copperhead). REPRODUCTION.** Robust estimates of lifetime reproduction in female New World pitvipers exist only for several taxa, and in particular *Crotalus horridus* (Timber Rattlesnake). Here, we present data from a wild female *Agkistrodon contortrix* that suggests this species' reproductive lifespan is protracted, similar to *C. horridus* from New York.

On 24 August 2001, a pregnant female *A. contortrix* (SVL = 62.2 cm, tail length = 8.5 cm, mass = 165 g) was captured at our study site (Fig. 1). The area is a 485-ha parcel of basalt trap rock ridge ecosystem located 4.75 km NW of Meriden, Connecticut (Smith et al. 2009. Herpetol. Monogr. 23:45–73). She produced a litter of 3 healthy offspring in the laboratory on 5 September 2001. Her post-birth mass was 99.3 g. She was subsequently PIT tagged and released at the exact location of capture.

The female was subsequently captured at the same site (within 1 m) on 25 July 2008, 28 May 2010, 26 July 2011, and 12 August 2013. On 25 July 2008 she appeared pregnant (SVL = 65.3 cm, tail length = 8.5 cm, mass = 340 g) and produced a litter of 6 healthy offspring in the laboratory on 2 September 2008. Her post-birth mass was 162 g. On 28 May 2010, although she did not appear pregnant (SVL = 65.5 cm, tail length = 9.0 cm, mass = 340 g), she was nonetheless brought back to the laboratory for observation. She did not produce a litter in 2010. On 26 July 2011 she appeared pregnant (SVL = 67.6 cm, tail length = 9.0 cm, mass = 274 g) and was brought to the laboratory. She produced a litter of 8 healthy offspring on 28 August 2011. Her post-birth mass was 199 g. On 12 August 2012 she was recaptured at the same location and appeared pregnant (SVL = 67.8 cm, tail length = 9.0 cm, mass = 262

g). She produced a litter of 6 healthy offspring in the laboratory on 31 August 2013. Her post-birth mass was 155.2 g.

From her initial capture on 24 August 2001 until her last capture on 12 August 2013, we documented production of four litters by this female. Additional unobserved litters are possible from 10 October 2001 (when she was released following her first litter) to 25 July 2008 (when she was captured prior to her second litter). Based on her size and indisputable evidence of sexual maturation at the initial capture, we conservatively estimated her age in August 2013 to be 15 years old. Accordingly, we document her reproductive lifespan to be at least 12 years.

Long-term data on wild female *C. horridus* indicate that reproductive senescence is delayed or absent in this species' life history (Brown 1991. Herpetologica 47:101–115). Our data on *A. contortrix* are consistent with this suggestion. We encourage others to collect long-term data on individuals of other pitviper species to better understand this important life history characteristic.

We thank J. Victoria and L. Fortin, Connecticut Department of Environmental Protection Wildlife Division, for providing the necessary permits. C. Annicelli, S. Berube, H. Gruner, S. Horwitz, J. Marzolf, and T. Tyning provided numerous favors. ***APOSTOLEPIS MULTICINCTA*. DIET.** *Apostolepis multicincta* (family Dipsadidae) is a small, fossorial snake endemic to the inter-Andean dry valleys of Bolivia in the Departments of Santa Cruz (Reiche and Embert 2005. J. Herpetol. 39:379–383) and Chuquisaca (Cortez, *in press*. Kempffiana). Little information is available on the natural history of this species, including its diet. The only known prey item is a blind snake (*Leptotyphlops striatula* = *Epictia striatula*; Embert and Reichle 2003. Salamandra 39:249–252). Herein we document a new prey item for *A. multicincta*. On 16 June 2014 at 1500 h we captured an adult *A. multicincta* (male; SVL = 385 mm; tail length = 50 mm; head width = 5.6 mm) crossing the road in the community of Pacay, Florida Province, Santa Cruz Department, Bolivia (18.039722°S, 64.142222°W, WGS 84; elev. 1294 m). Several hours later, while in captivity, the *A. multicincta* regurgitated a juvenile *Amphisbaena cegei* (male; SVL = 140 mm; tail length = 15 mm). This is the second known prey item for *A. multicincta*, and the first instance of an amphisbaenian in its diet. Both individuals were deposited in the Herpetology Collection in the Noel Kempff Mercado Museum, Santa Cruz de la Sierra, Bolivia (*A. multicincta* MNKR 5355; *A. cegei* MNKR 5356).

***ASPIDITES MELANOCEPHALUS* (Black-headed Python). DIET.** Pythons (Pythonidae) are among the largest native predators in many Australian terrestrial communities. However, interactions between these species and the suite of introduced mammalian predators that now dominate much of Australia have rarely been reported. On 7 July 2014, we observed a road-killed *A. melanocephalus* (total length ca. 1.5–2 m) on the Gibb River Road, Western Australia, just west of the turnoff to Windjana Gorge Road in open savanna woodland (Fig. 1). Inspection of the stomach contents revealed three feral cat kittens (*Felis catus*). Based on their small size (ca. 150 mm head–body length), folded ears and closed eyes, these cats were less than a few weeks old and had been consumed in one session, presumably when the python found them in a den. The posterior-most cat was near fully digested, while the other two cats were intact.

Australia's mammal fauna has undergone systematic declines across most of the continent and direct predation by introduced predators (i.e., feral cats; red foxes) is widely considered a key threatening process (Short and Smith 1994. J. Mammal. 75:288–297). Populations of some native predators have clearly shifted to prey on comparatively abundant introduced mammals (e.g., rabbits, house mice; Heard et al. 2004. Austral Ecol. 29:446–460). However, although feral cats have played an important role in the decline of many native species, they have not been considered as potential prey for many native predators. This observation suggests that feral cats, which are relatively abundant and widespread throughout Australia, could be a significant food resource for some large native predators, such as *A. melanocephalus*.

FIG. 1. Road-killed *Aspidites melanocephalus* on the Gibb River Road, Western Australia, with three *Felis catus* it had consumed.

***BOA CONSTRICTOR* (Boa Constrictor). DIET.** *Boa constrictor* is an opportunist and generalist predator occurring throughout Central and South America (Henderson et al. 1995. Herpetol. Nat. Hist. 3:15–27). Its diet includes mainly mammals, reptiles, and birds (Pizatto et al. 2009. Amphibia-Reptilia 30:533–544; Bernarde

FIG. 1. A) *Patagioenas picazuro* (Picazuro Pigeon) predation by *Boa constrictor*. B) Google Earth satellite image showing urban fragment where predation took place (arrow), in Campo Grande, MS, Brazil.

and Abe 2010. Biota-Neotrop. 10:167–173). Although predation on wild birds by *B. constrictor* is well documented (e.g., Pizatto et al. 2009, *op. cit.*; Barbier and Rocha-Santos 2014. Herpetol. Rev. 45:140), herein we provide the first report of *B. constrictor* predation on *Patagioenas picazuro* (Picazuro Pigeon: Columbidae), in an urban forested fragment.

The observation occurred on 20 Sep 2010 in a forest clearing at the Natural Heritage Private Reserve of the Universidade Federal de Mato Grosso do Sul (NHPR/UFMS), Mato Grosso do Sul, Campo Grande, Brazil (20.5082°S, 54.6162°W; datum WGS84). At 0857 h, we found a *B. constrictor* constricting and swallowing a *P. picazuro* (Fig. 1A). The NHPR/UFMS fragment has an area of approximately 50 ha of dense savannah within a highly urbanized landscape. Despite the relatively small size of the fragment (Fig. 1B), our observation highlights the importance of these remaining protected areas as refuges for species and communities threatened by urban development.

We acknowledge Conselho Nacional de Desenvolvimento Científico e Tecnológico (CNPq) and Coordenação de Aperfeiçoamento de Pessoal de Nível Superior (CAPES) for financial support. We are grateful to Rudi Laps, Franco L. Souza, and Vanda L. Ferreira for helping in species identification and Cynthia P. A. Prado, Franco L. Souza, and Harry W. Greene for critically reviewing the manuscript.

LUCIANA V. DA SILVA, Programa de Pós- Graduação em Biologia Vegetal (e-mail: lucimariie@hotmail.com); **GABRIEL P. FAGGIONI**, Programa de Pós- Graduação em Ecologia e Conservação, Centro de Ciências Biológicas e da Saúde, Universidade Federal de Mato Grosso do Sul, 79.070-900, Av. Costa e Silva, Campo Grande, MS, Brazil (e-mail: faggioni@hotmail.com).

***BOA CONSTRICTOR* (Boa Constrictor). DIET.** *Boa constrictor* is a widely distributed, semiarboreal, mostly nocturnal, large-bodied snake (Greene 1983. *In* Janzen [ed.], Costa Rican Natural History, pp. 380–382. Univ. Chicago Press, Chicago, Illinois). These generalist, opportunistic, sit-and-wait predators are known to feed on a variety of prey, with endothermic animals comprising a large proportion of the diet of adult specimens (Pizzatto et al. 2009. Amphibia-Reptilia 30:533–544). Previous accounts on mammalian prey include opossums, bats, rats and mice, rabbits, squirrels, porcupines, tamanduas, mongooses, agoutis, coatis, armadillos, sloths, deer, ocelots, and monkeys (Reed and Rodda 2009. Giant Constrictors: Biological and Management Profiles and an Establishment Risk Assessment for Nine Large Species of Pythons, Anacondas, and the Boa Constrictor. U.S. Geological Survey Open-File Report 2009–1202, Reston, Virginia. 302 pp.). On 29 May 2012, we obtained an adult female *B. constrictor* (total length ca. 210 cm) from a local farmer (who thought it to be a *Lachesis stenophrys* [Matabuey or Bushmaster]) on the southern slope of Reserva Natural Cerro Musún (12.96°N, 85.23°W, datum WGS84; 650 m elev.), Dept. Matagalpa, Nicaragua. The farmer had killed the snake the previous morning at ground level in his crop field, situated at the edge of a relatively large and well preserved premontane wet forest. In the snake's stomach, we found a recently ingested, full-grown *Potos flavus* (Kinkajou: Procyonidae: Carnivora), a strictly nocturnal and mainly frugivorous and arboreal mammal (Ford and Hoffmann 1988. Mammalian Species 321:1–9). The snake had swallowed the Kinkajou head-first. To our knowledge, this is the first report of Kinkajou in the diet of *B. constrictor*.

FIG. 1. Ingestion of *Potos flavus* (Kinkajou) by *Boa constrictor* at Reserva Natural Cerro Musún, Dept. Matagalpa, Nicaragua.

GALINDO-URIBE**, Grupo de Ecofisiología, Comportamiento y Herpetología, Universidad de los Andes, Bogotá, Colombia (e-mail: dm.galindo48@uniandes.edu.com).

***COLUBER* (= *MASTICOPHIS*) *BILINEATUS* (Sonoran Whipsnake). DIET.** Avian nest predation by snakes has been reported infrequently, but may account for as much as 90% of all nest predation (Weatherhead and Blouin-Demers 2004. J. Avian Biol.

FIG. 1. *Coluber bilineatus* swallowing a *Zenaida asiatica* (Mourning Dove) egg in Sonora, México.

35:185–190). *Coluber bilineatus* is a common snake in the Sonoran Desert that is semiarboreal to arboreal and is most commonly observed in brush and trees (Jones 2014. Arizona Wildlife Views: 43). The diet of *C. bilineatus* is known to consist of lizards (Bezy and Enderson 2003. Sonoran Herpetol. 16:16–17) and mammals (Camper and Dixon 2000. Texas J. Sci. 52:83–92). Here we document the first report of bird eggs as food items for *C. bilineatus*.

On 13 August 2013 at 1100 h, we observed an adult *C. bilineatus* (total length ca. 1700 mm) predating the nest of a *Zenaida asiatica* (Mourning Dove) at La Cieneguita, 12 km from Mazocahui, municipality Baviacora, Sonora, México (29.539253°N, 110.015°W; datum WGS84). The snake climbed to the nest ca. 3.5–4 m above the ground of a live mesquite (*Prosopis velutina*). The dove fought for a few seconds but it was unable to protect the eggs and flew away. The snake proceeded to swallow the first egg (Fig. 1), but dropped the second egg while trying to swallow it. It searched for more eggs, but not finding any, eventually departed in response to our presence. Photos are deposited in the Colección Científica de Vertebrados de la Universidad Autónoma de Ciudad Juárez.

ANA GATICA-COLIMA, Universidad Autónoma de Ciudad Juárez, ICB, Departamento de Ciencias Químico Biológicas, Laboratorio de Ecología y Biodiversidad Animal, Anillo Envolvente del PRONAF y Estocolmo s/n, CP 32310, Ciudad Juárez, Chihuahua, México (e-mail: agatica@uacj.mx); **ALDO HIRAM GUTIÉRREZ-SALDAÑA** (e-mail: aldohiram@gmail.com), **ANTONIO OROZCO-AVÍTIA** (e-mail: avitia65@ciad.mx), **ROSA IDALY MORALES-ESTRADA** (e-mail: idalyum@yahoo.com.mx), and **JESÚS ALBERTO JIMÉNEZ-LEYVA** (e-mail: funjidos@yahoo.com.mx), Centro de Investigación en Alimentación y Desarrollo (CIAD A.C.), Coordinación de Tecnologías de Alimentos de Origen Vegetal (CTAOV), Laboratorio de Biotecnología de Plantas y Hongos, Carretera a La Victoria Km 0.6 C.P. 83304, Hermosillo, Sonora, México.

***COLUBER (= MASTICOPHIS) FLAGELLUM* (Coachwhip). DEFENSIVE BEHAVIOR.** Speed and retreat into bushes is the most common escape behavior seen in racers and whipsnakes (BHB, pers. obs.). Here we report an unusual escape behavior of a *Coluber flagellum* crawling up a Giant Saguaro (*Carnegia giantea*). Robert and Jamie Dieterich saw a *C. flagellum* (total length ca. 100 cm) in the shade of the veranda of their house on their Flying D Ranch, near Signal, Mohave Co., Arizona, USA (34.50864°N, 113.6304°W; datum WGS 84) at about l500 h on 17 April 2014. Apparently reluctant to go from the 30°C shade into the hot sun, it

FIG. 1. *Coluber flagellum* crawling up a Saguaro Cactus near Signal, Arizona, USA.

rattled its tail and made strikes at a broom used to move it away from the house. Finally the snake left the shade, traveled 3 m to and up 1.5 m on a 7-m tall Saguaro (Fig. 1). Distractions caused the observers to leave the area for about 5 min and on their return the snake had disappeared. While the snake was still visible, the spines on the cactus would deter most potential predators until further escape was possible.

BAYARD H. BRATTSTROM, Horned Lizard Ranch, P.O. Box 166, Wikieup, Arizona 85360, USA (e-mail: bayard@hughes.net); **JAMIE K. DIETERICH** and **ROBERT DIETERICH**, Flying D. Ranch, P.O. Box 132, Wikieup, Arizona 85360, USA.

***COLUBER (= MASTICOPHIS) MENTOVARIUS* (Neotropical Whipsnake). PREDATION.** Although snake predation by raptors is common and well-documented (Mitche and Fischer 2008. Banisteria 31:54–56), there are no records to my knowledge of *Coluber mentovarius* being part of the diet of any *Buteo* species.

FIG. 1. Head of a *Coluber mentovarious* found with feathers in its mouth, suggesting predation by a raptor.

Knight and Erickson (1976. Raptor Research 10:108–111) reported a high prevalence of snakes in the diet of a population of *Buteo jamaicensis* (Red-tailed Hawk) from north-central Washington, along the Columbia River, USA; *Coluber constrictor* (North American Racer) was the most abundant reptile prey item. Also, Granzinolli and Motta-Junior (2007. Emu 107:214–222) reported eight individual snakes (all of them Colubridae) in a sample of 259 pellets and 3296 prey items from eight species of raptors of the orders Falconiformes and Strigiformes in southeastern Brazil.

On 12 July 2014 at 1802 h, I found the head of an adult *C. mentovarius* with feathers in its mouth in relictual oak forest near Zacatzonapa, Tixtla de Guerrero, Guerrero, Mexico (17.51639°N, 99.3572°W, datum WGS84; 1546 m elev.). Nearby, I saw a *Buteo* sp. resting in an oak tree, suggesting that the snake was preyed upon by the hawk and bit the bird's feathers in defense.

RICARDO PALACIOS-AGUILAR, Facultad de Estudios Superiores Iztacala, Universidad Nacional Autónoma de México, Carrera de Biología, Ap. Postal 314. Tlalnepantla de Baz 54090, Estado de México, México; e-mail: ricardopalaciosaguilar@gmail.com.

***CROTALUS LEPIDUS* (Rock Rattlesnake). DIET.** The diet of *Crotalus lepidus* includes arthropods, frogs, small rodents, lizards, and snakes (Ernst and Ernst 2003. Snakes of the United States and Canada. Smithsonian Institution Press, Washington, D.C. 668 pp.). Herein we report a new prey item in the diet of this species.

On 24 June 2013 at 1445 h, we collected a male *C. lepidus* with a perceptible diet item in Cañon San Isidro, which is located in Santiago, Nuevo Leon, México (25.378966°N, 100.310179°W, WGS84; elev. 1800 m). The snake was maintained in captivity for eight days until feces were released. Examination of the fecal material revealed numerous black keeled and mucronated scales, as well as a partially digested right leg, and a femur and phalangeal bones of a left leg. A comparison of the scales found in the samples with those from reptiles present in the area indicated that the scales belonged to the lizard *Sceloporus oberon* (Royal Lesser Minor Lizard), a species apparently common in the area. To the best of our knowledge this is the first report of *S. oberon* in the diet of *C. lepidus*. The snake was released at the site of capture.

Special thanks to V. Mata-Silva for reviewing a draft of this note.

JAVIER BANDA-LEAL (e-mail: javier_banda@hotmail.com), **DAVID LAZCANO**, **MANUEL NEVÁREZ- DE LOS REYES**, and **ALEJANDRO HUERECA-DELGADO,** Universidad Autónoma de Nuevo León, Facultad de Ciencias Biológicas, Laboratorio de Herpetología, Apartado Postal # 513, San Nicolás de los Garza, Nuevo León, C.P. 66450, México.

***CROTALUS MOLOSSUS* (Black-tailed Rattlesnake). REPRODUCTION.** Reproductive bimodality has been observed in several North American pit vipers, most notably *Crotalus atrox* (Western Diamond-back Rattlesnake), but has not been documented in *C. molossus molossus* (Ernst 1992. Venomous Reptiles of North America. Smithsonian Institution Press, Washington D.C. 236 pp.). Therefore, we were surprised when we discovered one of our radio-telemetered *C. m. molossus* engaged in courtship with an unmarked female on 5 March 2014 at 1225 h. We observed the snakes on an east-facing talus slope on Tumamoc Hill, a national environmental study site where our lab is located, within 3.2 km of downtown Tucson, Arizona, USA, (32.2169°N, 111.0031°W, datum NAD83). Courtship behavior included persistent chin-rubbing and tongue-flicking by the male along the female's dorsum, even as the female began to move slowly into the talus. We left the site at 1256 h to reduce disturbance to the animals.

PHOTO BY LILY WALSH

FIG. 1. Pair of *Crotalus molossus molossus in copulo*, as evidenced by the bulge immediately anterior to the female's cloaca, 5 March 2014 in Tucson, Arizona, USA.

We revisited the site at 1710 h, at which time we observed the two snakes *in copulo* ($T_{ambient}$ = 23.3°C, $T_{substrate}$ = 33.0°C, relative humidity = 36%, cloud cover = 85%). We were able to determine that the snakes were copulating, because the female had a noticeable bulge immediately anterior to her cloaca (Fig. 1), and she was clearly dragging the male with her as she moved. We left again at 1720 h, when it became apparent that the female was attempting to hide in the talus, possibly in reaction to our presence. The following day at 1139 h, the male had moved ca. 20 m, and the female was no longer present.

Although spring mating in *C. m. molossus* has not been observed in the past, histological findings indicate that males are at least capable of spermiogenesis as early as May, resulting in the presence of viable sperm in the vasa deferentia (Goldberg 1999. Texas J. Sci. 51:321–328). In contrast, males found in March–April were characterized by either regressed or recrudescent testes, which would preclude successful insemination. With regard to females, a few individuals were found with oviductal eggs as early as April; however, fertilization from stored sperm seems a more plausible explanation for early ovulation. Regardless, these histological findings do not coincide with the timing of our observation. Although Goldberg's (*op. cit.*) data include 59 individuals from Arizona, he only provides locality data as county of origin. Therefore, detailed histological information from *C. m. molossus* found at our study site would be required for a more robust interpretation of our observation.

Observations of reproductive behavior in *C. molossus nigrescens* provide additional context. Successful copulation was observed in this species on 1 February 1978, 28 May 1973, and 2 March 1974. The second two observations were made of captive animals, and the first was in the field (Ernst, *op. cit*). The range of *C. m. nigrescens* encompasses central Mexico between the states of Durango and Oaxaca, an area that typically experiences mild winters without hard freezes (Campbell and Lamar 2004. The Venomous Reptiles of the Western Hemisphere. Cornell University Press, New York. 870 pp.). Given the climatic differences faced by the two subspecies, it seems plausible to suggest that spring mating might occur more commonly in low-elevation/low-latitude populations of *C. m. molossus*, such as our study population in Arizona.

***CROTALUS TOTONACUS* (Totonacan Rattlesnake). DIET.** Like most of the larger members of its genus, *Crotalus totonacus* is known to prey on small mammals and birds. Reports include a juvenile containing rodent hair (Armstrong and Murphy 1979. Univ. Kansas Mus. Nat. Hist. Spec. Publ. 5:1–88), and mammal hair and bird feathers (Klauber 1972. Rattlesnakes: Their Habits, Life Histories, and Influence on Mankind. Vol. I & II. 2nd ed. University of California Press. Berkeley, California. 1533 pp.). Specific prey items documented for the species are limited. Martin (1958. Misc. Publ. Mus. Zool. Univ. Michigan 101:1–102) found a *Neotoma* sp. (cave rat) and a *Sciurus alleni* (Allen's Tree Squirrel) in the stomachs of two specimens from Tamaulipas, México. Here we report the first record of an additional species, *Spermophilus* (*Otospermophilus*) *variegatus* (Rock Squirrel).

At 1342 h on 6 June 2007, 9.37 km (airline) SW of the junction of Mex Hwy 85 and N. L. State Hwy 20, on a dirt pathway S of Hwy 20, in the municipality of Santiago, Nuevo León, México (25.335934°N, 100.192566°W, datum WGS84; elev. 1282 m), one of us (SEOH) observed an adult *C. totonacus* (total length ~1.8 m) eating a squirrel. When first seen, the snake had already swallowed the head of the squirrel (Fig. 1). The snake was observed for about 5 min during which time it dragged the food item about 2 m to some scrub cover and was left alone to finish eating. Additionally we report here the contents of an unpublished thesis (Vallejo-Gamero 1981. Taxonomía y distribución de la familia Crotalidae en el estado de Nuevo León, México. Tesis Inédita, Facultad de Ciencias Biológicas, Universidad Autónoma de Nuevo León, México. 49 pp.) that noted stomach contents of *C. totonacus* included *Neotoma* sp. and *Didelphis* sp. (opossum). Unfortunately the specimens the report was based on are no longer present in the UANL collection for verification. We thank Juan Cruzado-Cortés for help with identifying the squirrel.

FIG. 1. A *Crotalus totonacus* preying on a *Spermophilus variegatus* (Rock Squirrel) in the municipality of Santiago, Nuevo León, México.

FARR, Houston, Texas 77096, USA (e-mail: williamfarr@sbcglobal.net); **MANUEL NEVÁREZ DE LOS REYES, DAVID LAZCANO**, Universidad Autónoma de Nuevo León, Facultad de Ciencias Biológicas, Laboratorio de Herpetología, Apartado Postal 513, San Nicolás de los Garza, Nuevo León, C.P. 66450, México; **SADOT EDGARDO ORTIZ-HERNÁNDEZ,** Parque Nacional Cumbres de Monterrey, Nuevo León, México.

***DRYMARCHON MELANURUS* (Central American Indigo Snake). DIET.** *Drymarchon melanurus* is known to feed on a great variety of prey including fishes, eggs, frogs, turtles, lizards, snakes, birds, and mammals (Scott 1983. *In* Janzen [ed.], Costa Rican Natural History, pp. 380–382. Univ. Chicago Press, Chicago, Illinois). In Nicaragua, the only dietary record of this species includes a *Leptodactylus savagei* (Travers et al. 2011. Herpetol. Rev. 42:399–403). Herein we report the first record of predation by *D. melanurus* on a Swamp Eel.

FIG. 1. Predation by *Drymarchon melanurus* on *Synbranchus marmoratus*, at Lost Canyon Nature Reserve, San Juan de Dios, El Jicaral, Dept. León, Nicaragua.

At 1715 h on 18 February 2014, at Lost Canyon Nature Reserve (12.70582°N, 86.41777°W, datum WGS84; 140 m elev.), San Juan de Dios, El Jicaral, Dept. León, Nicaragua, a *D. melanurus* (total length ca. 180 cm) was encountered pulling a Swamp Eel (*Synbranchus marmoratus*; total length ca. 80 cm) out of a 2.3-m wide stream surrounded by secondary vegetation. The snake firmly grabbed the eel with its posterior teeth while pulling it out of the water by coiling its body uphill. The eel showed evidence of the attack in the middle and posterior part of its body. The snake never tried to constrict and did not release the eel, which hissed and struggled for about 10 min. After ca. 15 min. they were left alone because the snake was clearly concerned with the presence of human observers. At that point, the snake had managed to pull the eel 1 m up and about 50 cm horizontal from the stream to the adjacent spiny vegetation. The habitat was lowland dry forest in transition to arid habitat (Holdridge 1967. Life Zone Ecology, rev. ed. Tropical Science Center, San José, Costa Rica. 206 pp.). We thank Eric van den Berghe for identification of the eel.

JAVIER SUNYER, Museo Herpetológico de la UNAN-León, Departamento de Biología, Facultad de Ciencias y Tecnología, Universidad Nacional Autónoma de Nicaragua-León, León, Nicaragua (e-mail: jsunyermaclennan@gmail.com); **RICHARD LEONARDI**, Lost Canyon Nature Reserve, Nicaragua (e-mail: r.k.leonardi@gmail.com, www.Lost-Canyon.org).

***ERYX JACULUS* (Sand Boa). ALBINISM.** *Eryx jaculus* is a diurnal, burrowing snake and is the only member of the family Boidae in Europe. It ranges from the Balkans, Turkey, and Greece to central Asia, the Middle East, and Mediterranean North Africa. In Greece it is present on the mainland and many islands of the Aegean and the Ionian Seas (Valakos et al. 2008. The Amphibians and Reptiles of Greece. Edition Chimaira, Frankfurt am Main, Germany. 463 pp.). On 14 May 2014, at 1908 h, we found an albino adult *E. jaculus* under a stone near the port of Aghios Georgios, Iraklia, Greece (36.8611°N, 25.4701°E; datum WGS84). The specimen (Fig. 1; SVL = 300 mm; tail length = 30 mm; 31.6 g) was found 50 m from another adult *E. jaculus* with a typical pattern. Although

PHOTO BY ALEX SLAVENKO

FIG. 1. Albino *Eryx jaculus* found near the port of Aghios Georgios, Iraklia, Greece.

albinism has been reported to occur in other boid species (e.g., *Lichanura trivirgata;* Klauber 1972. Rattlesnakes: Their Habits, Life Histories, and Influence on Mankind. University of California Press, Berkeley, 2 vols. 1533 pp.), we know of no other cases of albinism in this species.

***HYDROPHIS* (= *PELAMIS*) *PLATURA* (Yellow-bellied Seasnake). INTERACTION WITH DOLPHINS.** *Hydrophis platura* is the only fully pelagic sea snake. It is thought to be predominantly a passive drifter that concentrates around ocean slicks, where it sometimes forms aggregations into the millions (Campbell and Lamar 2004. Venomous Reptiles of the Western Hemisphere. Cornell University Press, Ithaca, New York. 870 pp.). Little is known about biotic interactions of *H. platura*. It eats fishes and probably has few predators because it is unpalatable to many fishes and may have toxic flesh (Campbell and Lamar, *op. cit.*).

At ~1015 h on 7 November 2013, one of us (EL) was swimming with a pod of about half a dozen *Tursiops truncatus* (Common Bottlenose Dolphins) in Banderas Bay, Jalisco, Mexico (20.7031078°N, 105.3278205°W; datum WGS84), when two of the dolphins began interacting with an adult *H. platura* (Fig. 1; total length ca. 70 cm based on photographs). Over a period of 6–7 min, the two dolphins pushed the snake around in the water with their heads and repeatedly threw it into the air using their tails. The snake did not react in any obvious way, only continued to swim.

Although wild and captive delphinids occasionally manipulate other animals for functional purposes (e.g., Smolker et al. 1997. Ethology 103:454–465), the majority of reports of these kinds of interactions seem to serve no particular purpose and are categorized as play. Social object play using plants or animals that do not serve as prey often involves pushing these animals around, passing them from one part of the body to another or among individuals, or chasing and grabbing them only to release them before chasing again (Janik 2015. Current Biol. 25:R7–R8). These behaviors are often accompanied by splashing, aerial displays, and social interactions (Mann and Smuts 1999. Behaviour 136:529–566). Because the behavior of the dolphins we observed fit this description, we suggest that the dolphins were playing with the snake. If this was indeed the case, this is the first documentation of dolphins playing with a marine reptile.

Dolphins do not appear to prey upon *H. platura*. Kropach (1972. PhD dissertation, The City University of New York), reporting the unpublished data of other investigators, stated that

PHOTOS BY EDUARDO LUGO

FIG. 1. *Tursiops truncatus* (Common Bottlenose Dolphins) seemingly playing with a *Hydrophis* (= *Pelamis) platura* (Yellow-bellied Seasnake) in Banderas Bay, Jalisco, Mexico.

stomach contents of 214 dolphins examined from areas of the eastern Pacific where *H. platura* was plentiful contained no sea snakes, and Heatwole (1975. *In* W. A. Dunson [ed.], The Biology of Sea Snakes, pp. 233–249. University Park Press, Baltimore, Maryland) concluded that *H. platura* are nearly free from predation. Two reports of pinnipeds, both of which became ill, consuming *H. platura* suggest that the snakes are unpalatable to marine mammals. In addition, the venom of *H. platura* is largely neurotoxic and is probably highly potent. Although only a few fatal bites to humans have been reported, the potential for fatal bites to marine mammals exists.

ANDREW M. DURSO, Department of Biology, Utah State University, Logan, Utah 84322, USA (e-mail: amdurso@gmail.com); **MARIA EUGENIA RODRIGUEZ,** and **EDUARDO LUGO,** Wildlife Connection, Puerto Vallarta, Jalisco, Mexico, C.P. 48328.

***LEPTODEIRA SEPTENTRIONALIS* (Northern Cat-eyed Snake). DIET AND PREDATION.** Beginning at 1838 h on 30 May 2014 at the Caves Branch Jungle Lodge in Belize, we observed an encounter between a *Leptodeira septentrionalis* and an *Incilius valliceps* that appeared to have initiated as a predation attempt by the toad on the snake. The toad (SVL ca. 9 cm) had the dorsal portion of the snake's head in its mouth (Fig. 1); however, the toad was motionless and the snake (with its head in the toad's mouth) was retracting backwards up a stone wall into a crevice, pulling the toad with it. The snake's lower jaw was beneath the lower jaw of the toad, meaning that teeth of the snake's upper jaw were undoubtedly imbedded in the toad's lower mouth, thereby allowing the snake to envenom the toad, indicated by the toad's lack of motion (for information on toxicity of venom within

PHOTOS BY RICHARD ENGEMAN

FIG. 1. *Leptodeira septentrionalis* found with the dorsal portion of its head in the mouth of an *Incilius valliceps* in Belize.

FIG. 2. In a quick motion 20 min after observations were initiated, the *Leptodeira septentrionalis* removed its head from inside the mouth of the *Incilius valliceps* and captured the toad's snout in its mouth.

genus *Leptodeira* see Weinstein et al. 2014. Clin. Toxicol. 52:277–282). Within 2 min the snake had retracted nearly its whole body into the crevice, but it was also clear that the toad would not fit into it (Fig. 1). At approximately 1858 h, the snake made a quick motion to simultaneously extract its head from the immobilized toad and put the toad's snout in its mouth. It then began an attempt to swallow the toad (Fig. 2). To do so the snake gradually began to exit the crevice and stretch downwards. By 1941 h, the snake had engulfed nearly the whole head of the toad. The next morning the toad was found dead about 2 m from where the encounter was first observed. There was no indication of the fate of the snake. Our only explanation for the encounter was that the toad attempted to predate the snake, but the snake was able to bite inside the toad's mouth to envenom and kill the toad. This provided the counter-opportunity for the snake to attempt to eat the toad, which may have been too large to consume.

RICHARD M. ENGEMAN, National Wildlife Research Center, 4101 LaPorte Ave., Fort Collins, Colorado 80521-2154, USA (e-mail: richard.m.engeman@aphis.usda.gov); **CARRIE ENGEMAN**, 2485 Pelican Cove, Windsor, Colorado 80550, USA.

***OXYRHOPUS OCCIPITALIS*. MELANISM.** Melanism is an unusually high amount of black pigment within a particular individual (Gilhen and Scott 2014. Can. Field-Nat. 128:63–71). Melanism may provide advantages for thermoregulation and reproduction (Clusella-Trullas et al. 2007. J. Therm. Biol. 32:235–245) and has been described as common and highly variable in snakes (Lorioux et al. 2008. Amphibia-Reptilia 29:1–5).

On 16 October 2013 at 1128 h, a melanistic adult female *Oxyrhopus occipitalis* (Fig. 1; SVL = 680 mm; tail length = 198 mm) was collected at the upland forest in Reserva Extrativista Beija Flor Brilho de Fogo (0.8044°N, 52.212692°W, datum WGS 84; elev. 98.4 m), municipality of Pedra Branca do Amapari, Amapá state, Brazil, and deposited in the herpetology collection of Universidade Federal do Amapá (CECCAMPOS 00911). This record constitutes the first published account of melanism in *O. occipitalis* (Dipsadidae, Xenodontinae, Pseudoboini) from the eastern Amazon.

We are grateful to Edmilson G. Coelho (Secretaria Municipal do Meio Ambiente e Turismo) for providing logistic help in the Reserva Extrativista Beija Flor Brilho de Fogo. We thank Paulo S. Bernarde for help with the identification of the snake, and ICMBio for the license number 41443-1.

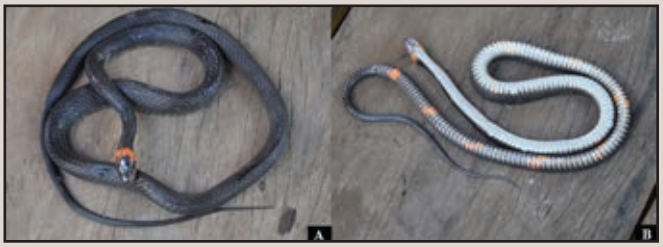

FIG. 1. Dorsal (A) and ventral (B) views of an adult female *Oxyrhopus occipitalis* displaying melanistic coloration.

CARLOS E. COSTA-CAMPOS (e-mail: eduardocampos@unifap.br), **PEDRO G. NERY SAMPAIO, JULIANA G. CORRÊA, YURI B. SILVA E SILVA, RAIMUNDO R. JESUS BAÍA, HÉLIO R. M. PAMPHILIO JÚNIOR, MAYARA F. M. FURTADO,** and **PEDRO F. FRANÇA,** Laboratório de Herpetologia, Departamento de Ciências Biológicas e da Saúde, Coordenação de Ciências Biológicas, Universidade Federal do Amapá, Campus Marco Zero, 68.903-419, Macapá, AP, Brazil.

***PANTHEROPHIS GUTTATUS* (Red Cornsnake). DIET.** *Pantherophis guttatus* is a common predator of small mammals and of

FIG. 1. *Pantherophis guttatus* with ingested *Falco sparverius* (American Kestrel) nestlings, Marion County, Florida.

bird eggs and nestlings, including those of *Colinus virginianus* (Northern Bobwhite) and various songbirds (Ernst and Ernst 2003. Snakes of the United States and Canada. Smithsonian Inst. Press, Washington, D.C. 668 pp.; Miller and Leonard 2010. Southeast. Nat. 9:395–402). Circumstantial evidence suggests that *P. guttatus* might occasionally prey upon eggs or nestlings of larger birds such as cavity-nesting birds of prey. We report here the first documented case of *P. guttatus* preying on *Falco sparverius* (American Kestrel) nestlings in a nest box located ca. 1 km W of Sparr, Marion Co., Florida, USA. Kestrels began incubating a clutch of five eggs on 21 March 2012, and three healthy 5-day-old nestlings and two unhatched eggs were observed on 24 April. When we returned on 14 May to band the 25-day-old nestlings, the nest box contained one unhatched egg and a *P. guttatus* (ca. 1.1 m total length) with three visible lumps from its ingested prey (Fig. 1). Kestrel nestlings typically average 100–105 g as they approach fledging. The nest box was located 4.6 m above ground on a utility pole surrounded by pastures and linear fencerows of oak woodlands.

KARL E. MILLER (e-mail: karl.miller@myfwc.com), and **ANNA FASOLI**, Fish and Wildlife Research Institute, Florida Fish and Wildlife Conservation Commission, 1105 SW Williston Road, Gainesville, Florida 32601, USA (e-mail: anna.fasoli@myfwc.com).

***PLATYCEPS NAJADUM* (Dahl's Whip Snake). MAXIMUM SIZE.** *Platyceps najadum* is found throughout the Balkans, Cyprus, the Middle East, and the Caucasus Mountains in dry, xeric habitat from sea level to 2000 m elev. An individual from Bulgaria is the largest known specimen with a maximum total length (TL) of 152 cm (Stojanov et al. 2011. Die Amphiben und Reptilien Bulgariens. Chimaira, Frankfurt am Main. 588 pp.).

Here we present a new maximum body size for *P. najadum* based on a female specimen found on the road in the vicinity of Rustavi, Kvemo Kartli Region, Georgia, near an industrial zone of a nitrogen fertilizer plant (41.536530°N, 45.067462°E; elev. 320 m), 25 September 2012. The specimen was identified by N. Ananjeva and measured 172 cm TL with a tail length of 53 cm.

DAVID BEKOSHVILI, Laboratory of Vertebrate Animals Zoology, Institute of Zoology, Ilia State University, Cholokashviliave., 3/5, 0162 Tbilisi, Georgia (e-mail: daviti57@mail.ru); **IGOR V. DORONIN**, Department of Herpetology, Zoological Institute of Russian Academy of Sciences, St. Petersburg 199034, Russia (e-mail: ivdoronin@mail.ru).

***POPEIA FUCATA* (Thai Peninsula Pit Viper). REPRODUCTION.** *Popeia fucata* is known from parts of Myanmar, Thailand, and Peninsular Malaysia (Das 2010. A Field Guide to the Reptiles of South-east Asia, Myanmar, Thailand, Laos, Cambodia, Vietnam, Peninsular Malaysia, Singapore, Sumatra, Borneo, Java, Bali. New Holland Publishers, UK. 376 pp.). *Popeia fucata* (as *Trimeresurus popeiorum*) has litters of 7–12 young (Cox et al. 1998. A Photographic Guide to Snakes and other Reptiles of Thailand and South-east Asia. Asia Books Co., Ltd. Bangkok. 144 pp.). We know of no published information on reproduction of male *P. fucata*. In this note we present information on the minimum size for maturity in male *P. fucata*.

Seven *P. fucata* males were examined (mean SVL = 450.4 mm ± 124.8 SD, range = 242–592 mm) from Peninsular Malaysia collected by LLG during 2002, 2004 to 2006, and 2012 and deposited in the herpetology collection (LSUHC) of La Sierra University, Riverside, California, USA (by state): Kedah, LSUHC 6872, 7565, 7566, 6832; Perak, LSUHC 10664, 10665; Selangor, LSUHC 5098. The lower part of the body cavity was opened and the left testis was removed, embedded in paraffin, histological sections cut at 5 μm and stained by Harris hematoxylin followed by eosin counterstain. Histology slides are deposited in LSUHC.

Two stages were noted in the testicular cycle: 1) regressed, seminiferous tubules are reduced in size, spermatogonia and interspersed Sertoli cells are present; 2) spermiogenesis, seminiferous tubules are lined by sperm or clusters of metamorphosing spermatids. Juvenile males exhibiting regressed testes were LSUHC 242, SVL = 242 mm from July; LSUHC 10664, SVL = 364 mm from July; and LSUHC 7565, SVL = 403 mm from August. Adult males exhibiting spermiogenesis were LSUHC 6872, SVL = 452 mm from September; LSUHC 7566, SVL = 535 mm from August; LSUHC 6832, SVL = 565 mm from September; and LSUHC 5098, SVL = 592 mm from November. Thus, it appears that male *P. fucata* mature at ca. 450 mm SVL.

STEPHEN R. GOLDBERG, Whittier College, Department of Biology, Whittier, California 90608, USA (e-mail: sgoldberg@whittier.edu); **L. LEE GRISMER,** La Sierra University, Department of Biology, Riverside, California 92515, USA (e-mail: lgrismer@lasierra.edu).

***PSEUSTES POECILONOTUS* (Bird-eating Snake). PREDATION.** *Herpetotheres cachinnans* (Laughing Falcon) is a relatively common and widespread bird found in woodlands throughout Central and South America and has a diet consisting primarily of snakes (86% of the diet in a well-studied population in Guatemala [Parker et al. 2012. *In* D. F. Whitacre [ed.], Neotropical Birds of Prey: Biology and Ecology of a Forest Raptor Community, pp. 265–280. Cornell University Press, Ithaca, New York]). However, to our knowledge, *Pseustes poecilonotus* is not a known diet item (Sazima and Abe 1991. Stud. Neotrop. Fauna Environ. 26:159–169; Laurencio 2005. Herpetol. Rev. 36:188; DuVal et al. 2006. Biotropica 38:566–568; Parker et al., *op. cit.*). On 04 March 2014, at the Organization for Tropical Studies, La Selva Biological Station in northeastern Costa Rica (Heredia Province), we observed an *H. cachinnans* capture and then drop an adult *P. poecilonotus* (total length ca. 1.5 m) along the Sendero Surá trail, within the arboretum. AS initially spotted the falcon attacking the snake; the falcon flew 2 m off the ground with the snake, but dropped it as the snake struggled. RAS and AWJ arrived and observed the bird and snake for an additional 30 min. After dropping the snake, the falcon perched on a horizontal branch at the edge of the arboretum clearing, approximately 10 m above snake. It appeared that the falcon could no longer locate the snake, and after 30 min, the bird flew away without the snake. The snake was still alive after the bird flew, but its left eye was pierced, there were two punctures on the dorsal region of its head, a few

displaced dorsal scales ca. 5 cm from the nuchal region, blood on its broken jaw, and multiple punctures at ca. 1/3 the length of its body. We returned to the site at 1320 h and the snake remained coiled up in the same spot and was marginally responsive. We returned again the following morning at 0800 h and the snake was no longer present.

RALPH A. SAPORITO, Department of Biology, John Carroll University, University Heights, Ohio 44118, USA (e-mail: rsaporito@jcu.edu); **ANDREW W. JONES**, Cleveland Museum of Natural History, Cleveland, Ohio 44106, USA; **AMANDA SNOW**, Department of Earth & Space Science, Columbus State University, Columbus, Georgia 31907, USA.

***SISTRURUS CATENATUS CATENATUS* (Eastern Massasauga) AND *NERODIA SIPEDON SIPEDON* (Northern Watersnake). DIET AND FOREIGN OBJECT.** We examined the gut contents of *Sistrurus catenatus catenatus* (N = 13) and *Nerodia sipedon sipedon* (N = 17) found dead on a highway in Magnetawan First Nation, Ontario, Canada between 1 May and 31 August 2013. Necropsies determined that 5/13 (38.5%) *S. c. catenatus* and 3/17 (17.6%) *N. s. sipedon* had prey within their digestive systems. For *S. c. catenatus*, all identifiable prey items were parts of small mammals (fur, paws, and bones; average wet mass = 13.64 g), excluding a single adult *Opheodrys vernalis* (Smooth Greensnake), found in the gut of a juvenile *S. c. catenatus* (body size of both snakes could not be measured due to vehicular damage). Prey items identified from *N. s. sipedon* were both fish (whole, scales, and bones; average wet mass = 9.1 g) and unidentified small mammals (bones, tissue, and fur; average wet mass = 8.4 g). A similar (*S. c. catenatus*) or lower (*N. s. sipedon*) percentage of snakes we collected on a roadway had prey within their digestive tracts when compared to previous field studies that examined gut contents in individuals of these snake species collected from sites not associated with roads (Keenlyne and Beer 1973. J. Herpetol. 7:383–384; Shepard et al. 2004. Am. Midl. Nat. 152:360–368).

Both the presence of small mammal fur within *N. s. sipedon* and an *O. vernalis* within a juvenile *S. c. catenatus* are noteworthy as although these prey items have been documented previously, they are uncommon (Rowell 2012. The Snakes of Ontario: Natural History, Distribution, and Status. Art Bookbindery, Winnipeg, Manitoba. 411 pp.). However, an even more interesting item recovered from the necropsies was a fishhook (4.4 cm long) found within the intestines of a male *S. c. catenatus* (Fig. 1). The fishhook appeared to be a small J-hook with barbed end, typically used for fishing with bait. The fishhook had considerable corrosion, either from exposure to water or as a result of the stomach acid of the snake. The diet of adult *S. c. catenatus* is thought to consist predominately of small mammals; however, fish, crayfish, and amphibians have been documented as prey (Rubio 2010. Rattlesnakes of the United States and Canada. ECO Herpetological Publishing & Distribution, Rodeo, New Mexico. 307 pp.; Ernst and Ernst 2011. Venomous Reptiles of the United States, Canada and Northern Mexico. John Hopkins Univ. Press, Baltimore, Maryland. 352 pp.). As fish are known prey of this species, the snake may have inadvertently ingested the hook while consuming a living or dead fish previously hooked on a fishing line. Partially digested prey, consisting of mammal hair (wet mass = 10.74 g), was also recovered from the gut of this *S. c. catenatus*. The snake appeared to be in good body condition and the presence of relatively fresh prey in the gut suggests that it was still actively feeding despite having a fishing hook lodged in its intestines. To our knowledge this is the first documented account of a fishhook being recovered from the digestive system of *S. c. catenatus*.

***SISTRURUS TERGEMINUS EDWARDSII* (Desert Massasauga). DIET.** Massasaugas feed on a variety of prey, including invertebrates, frogs, lizards, and small mammals (Campbell and Lamar 2004. Venomous Reptiles of the Western Hemisphere. Comstock Publishing Associates, Ithaca, New York. 870 pp.), and their diet varies across their large geographic distribution. *Sistrurus catenatus* (Eastern Massasauga) feeds primarily on small mammals, while *S. tergeminus* (Western Massasauga) includes more lizards in the diet (Werler and Dixon 2000. Snakes of Texas. University of Texas Press, Austin. 437 pp.; Ernst and Ernst 2003. Snakes of the United States and Canada. Smithsonian Institution Press, Washington D.C. 668 pp.). At ~ 0030 h on 9 August 2014 we found a recently road-killed *S. tergeminus edwardsii* on U.S. Hwy 90, 17.3 km SE of Valentine, in Presidio Co., Texas, USA (30.48109°N, 104.36359°W; datum WGS84). Upon dissection the snake was found to contain two partially digested individuals of *Aspidoscelis inornata* (Trans-Pecos Striped Whiptail). To our knowledge this species is a novel prey item for *S. tergeminus* (Greene and Oliver 1965. Herpetologica 21:226–228; Werler and Dixon 2000, *op. cit.*; Ernst and Ernst 2003, *op. cit.*; Campbell and Lamar 2004, *op. cit.*). The snake and lizards were collected and deposited as SRSU 6616.

***STORERIA DEKAYI* (Dekay's Brownsnake). DIET.** *Storeria dekayi* is a small North American natricine snake that preys predominantly upon slugs and earthworms (Judd 1954. Copeia 1954:62–64; Gray 2013a. Herpetol. Rev. 44:527). Snails have also been reported as prey items of *S. dekayi* (Surface 1906. Pennsylvania Dept. Agric., Div. Zool., Monthly Bull. 4:114–208). However, observation of snails or their remains in the diet of free-ranging *S. dekayi* are scarce. In this note, I provide evidence of snail predation by free-ranging *S. dekayi* from northwestern Pennsylvania, USA.

Between 23 April and 13 June 2014, 20 fecal samples were collected from free-ranging *S. dekayi* from a site in Erie Co., Pennsylvania, USA (42.09375°N, 80.14180°W; datum WGS84). Fecal samples were placed in 70% isopropyl alcohol and examined with a dissecting microscope as per Gray (2013b. Bull. Chicago Herpetol. Soc. 48:157–165). Fecal samples from two female (SVL = 274 and 279 mm) and one male (SVL = 140 mm) *S. dekayi* each contained 1–2 jaws characteristic of snails in the family Succineidae (Fig. 1), 1–2 unidentified radulae, and plant material. The jaws of succineid snails have a median process on the cutting edge, and are unique among the terrestrial gastropods found in northeastern USA in having a relatively large squarish dorsal process (Pilsbry 1948. Land Mollusca of North America [north of Mexico], 2[2]. Acad. Nat. Sci. Philadelphia, Monogr. 3:i–xvii + 521–1113). Amber snails (*Succinea* spp.) are relatively abundant along the edge of a palustrine forest immediately west of the Erie Co. site.

No succineid shells were present in any of the fecal samples examined. In a previous study it was observed that slug shells, which are very brittle, pass through the digestive tract of *S. dekayi* intact (Gray 2013b, *op. cit.*). Therefore, if a shell or shell fragments from a succineid snail were ingested, they should have passed through undigested. Thus, it is most likely that the gastropods consumed by the three *S. dekayi* were extracted from their shells. Rossman and Myer (1990. J. Herpetol. 24:434–438) documented the process by which wild-caught *S. dekayi* extracted snails from their shells. The body of succineid snails is relatively large and barely retractable within the shell (Kerney and Cameron 1979. A Field Guide to the Land Snails of Britain and North-West Europe. William Collins Sons and Company, Ltd., London. 288 pp), offering little protection from gastropod-eating snakes. While preparing specimens for preservation, I observed that the body of succineid snails seemed to be easier to extract from their shells than snails with heliciform shells (e.g., snails in the family Polygyridae).

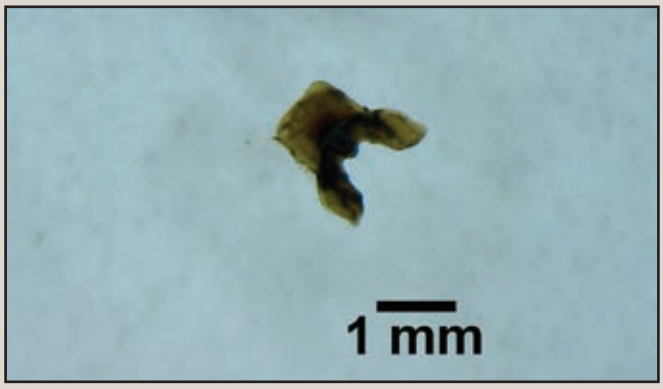

FIG. 1. A succineid snail jaw found in a fecal sample from a *Storeria dekayi*, Erie County, Pennsylvania, USA.

Storeria dekayi at this site preys predominantly on non-native slugs (e.g., *Arion hortensis* complex and *Deroceras reticulatum*) and to a lesser extent on the exotic earthworm *Lumbricus rubellus* (Gray 2013a, *op. cit.*; Gray 2014. J. N. Amer. Herpetol. 2014:28–39). The discovery of succineid jaws in three fecal samples demonstrate that these snails are also occasionally consumed and corroborate the importance of detecting this prey type using remnants of the body rather than those of the shell.

Thanks to Walter Meshaka, Jr., Tim Pearce, and George Pisani for their comments and suggestions regarding the manuscript.

BRIAN S. GRAY, Natural History Museum at the Tom Ridge Environmental Center, 301 Peninsula Drive, Erie, Pennsylvania 16505, USA; e-mail: brachystoma@hotmail.com.

***TELESCOPUS FALLAX* (European Cat Snake). REPRODUCTION.** *Telescopus fallax* is widely distributed in parts of the Middle East and southern Europe (Uetz and Hošek [eds.], The Reptile Database, http://www.reptile-database.org, accessed 14 June 2014). Bar and Haimovitch (2011. A Field Guide to Reptiles and Amphibians of Israel. Herzilya, Israel. 245 pp.) reported that *T. fallax* deposited clutches of seven eggs starting in June. The purpose of this note is to add information on the reproductive cycle of *T. fallax* from a histological examination of museum specimens from Israel, including the first information on timing of the testicular cycle.

A sample of 22 *T. fallax* consisting of 9 adult males (SVL = 450.9 mm ± 39.2 SD, range = 410–523 mm), 10 adult females (SVL = 460.9 mm ± 60.3 SD, range = 353–530 mm), 3 juvenile males (SVL = 359.3 mm ± 32.3 SD, range = 330–394 mm) collected 1948–2013 in Israel and placed in the Zoological Museum of Tel Aviv University (TAUM), by region was examined: HaGolan: (TAUM) 12432; HaSharon: (TAUM) 1421, 1650, 1673, 2851; HaShefla: (TAUM) 88; Shomeron (TAUM) 12858, 15281, 15728, 15732, 15735, 16482, 16709; Southern Coastal Plain (TAUM) 89, 2810, 9479, 13213; Upper Galil: (TAUM) 86; Yizreel Valley: (TAUM) 85, 1896, 3063; Yehudah Mts: (TAUM) 13618. A small slit was made in the left side of the abdomen and the left gonad was removed for histological examination. Enlarged ovarian follicles (> 4 mm) or oviductal eggs were counted only. Gonads were embedded in paraffin. Sections were cut at 5 μm and stained by Harris' hematoxylin followed by eosin counterstain. Histology slides are deposited at TAUM.

Three stages were observed in the testicular cycle (Table 1): 1) regressed, seminiferous tubules are reduced in size and contain spermatogonia with interspersed Sertoli cells; 2) recrudescence, a proliferation of germ cells occurs for the next period of spermiogenesis (= sperm formation), primary or secondary spermatocytes predominate; 3) spermiogenesis, seminiferous tubules are lined by sperm or clusters of metamorphosing spermatids. The period of sperm formation (spermiogenesis) occurred in summer and autumn (Table 1). The presence of regressed or recrudescent testes in spring with vasa deferentia packed with sperm, suggests *T. fallax* breeding occurs in the spring. The smallest reproductively active male (TAUM 1421) measured 415 mm SVL and was collected in March. It had a regressed testis, with a vas deferens containing sperm. *Telescopus fallax* males follow a testicular cycle similar to that exhibited by *Masticophis taeniatus* and *Pituophis catenifer* (reported as *P. melanoleucus*) from Utah, USA in which sperm formation occurs in autumn and mating occurs in spring when testes are regressed, utilizing sperm stored over winter in the vas deferens (Goldberg and Parker 1975. Herpetologica 31:317–322). This timing fits the

TABLE 1. Monthly stages in the testicular cycle of nine adult male *Telescopus fallax* from Israel; * = vas deferens containing sperm. These are the only vasa deferentia examined.

Month	N	Regressed	Recrudescent	Spermiogenesis
March	4	1*1*1*	1	0
April	1	0	1*	0
August	1	0	0	1*
September	1	0	0	1

FIG. 1. An adult *Thamnophis scalaris* and a *T. eques* found at the University Autonomus of State of Mexico. Both were found dead; the *T. scalaris* by unknown factors and *T. eques* by ophiophagy.

"aestival spermatogenesis" of Saint Girons (1982. Herpetologica 38:5–16).

Four stages were observed in the ovarian cycle (Table 2): 1) quiescent, no yolk deposition; 2) yolk deposition, basophilic yolk granules in ooplasm; 3) enlarged follicles > 4 mm; 4) oviductal eggs. The main period of female reproductive occurs in spring. The presence of one October female exhibiting yolk deposition in October may suggest some females commence ovarian activity in autumn. Clutch sizes were 5, 5, and 11. The smallest reproductively active female (TAUM 15281) measured 353 mm SVL, contained squashed oviductal eggs and was collected in May. In contrast to the report in Bar and Haimovitch (*op. cit.*) egg laying in *T. fallax* may begin as early as April (Table 2).

I thank Shai Meiri (TAUM) for permission to examine *T. fallax*, Erez Maza (TAUM) for facilitating the loan and the National Collections of Natural History at Tel Aviv University for providing samples of *T. fallax* for study.

STEPHEN R. GOLDBERG, Whittier College, Department of Biology, Whittier, California 90608, USA; e-mail: sgoldberg@whittier.edu.

***THAMNOPHIS SCALARIS* (Mexican Alpine Blotched Gartersnake) and *T. EQUES* (Mexican Gartersnake). PREDATOR-PREY RELATIONSHIPS.** At Área de Conservación e Investigación Ecológica, Bordo las Maravillas, in the El Cerrillo campus of the University Autonomus of State of Mexico (17 km NW of Toluca City, México; 99.68°W, 19.4°N, datum WGS84, elev. 2614 m), on 2 June 2012 (1159 h), we found an adult *Thamnophis scalaris* (SVL = 37 cm, tail length = 9.8 cm) that had eaten a *T. eques* (SVL = 22 cm SVL, tail length = 5.5 cm), near a seasonal pond bordered with *Salix* sp. The habitat was grassland surrounded by cultivated fields. The *T. scalaris* died by unknown causes; it had an injury from which the other snake was emerging (Fig. 1). *Thamnophis* spp. are poorly studied in México and *T. eques* has not been reported as part of the diet of *T. scalaris*. Several studies have determined that *T. scalaris* feed on frogs (*Hyla plicata*), salamanders (*Pseudoeurycea bellii* and *P. leprosa*), lizards (*Barisia imbricata* and *Sceloporus aeneus*), and rodents (*Peromyscus maniculatus*; Fouquette and Rossman 1963. Herpetologica 19:185–201; Sanchez-Herrera 1980. Bull. Maryland Herpetol. Soc. 16:9–18; Lemos-Espinal and Ballinger 1992. Herpetol. Rev. 23:117; Manjarrez et al. 2007. Southwest. Nat. 52:258–262). Previous reports at the same location found that *T. scalaris* preys on *Crotalus triseriatus* and that *T. scalaris* is consumed by *T. eques* (Venegas-Barrera and Manjarrez 2001. Herpetol. Rev. 32:187 and Manjarrez et al. 2007. Southwest. Nat. 52:258–262). This observation of ophiophagy among these sympatric snakes demonstrates that the predator-prey relationship is reciprocal.

I think all herpetologists know Kraig Adler, and many have received his generous help when it came to locating an obscure and ancient reference, or have been contacted by him asking about someone who, at some time, dealt with amphibians and reptiles around our places of residence. Adler's latest opus is the new edition, *aucta et reformata*, of the first volume of his *Contributions to the History of Herpetology*.

This series, which includes three published volumes (Adler 1989, 2007, 2012), began in 1989 when the SSAR and Adler presented the first volume during the First World Congress of Herpetology, held in Canterbury, England. Its formal aspects are outlined in the header of this review and on the last printed page of the book, so I will not dwell on it longer; instead, let's consider its contents. The two Latin words in the previous paragraph, *aucta* and *reformata*, were usually used by earlier herpetologists (even before the development of the word and the concept of herpetology) to indicate that the new work or edition was enhanced and revised with respect to a previous one. In fact, the main body (pages 5 to 133) is almost a facsimile of the first edition, with only few changes; the pagination is the same, and there are only two readily observable changes. One is the presence of several underlined names, a helpful reference to indicate that there is a biography related to each of them in some volume of the series, and the other is the presence of a myriad of footnotes, that frequently add valuable information to the already valuable content. Removed from the book are the sections by Applegarth (on the authors in taxonomic herpetology) and Altig (on the lineages of doctoral degrees in herpetology), both of which have been updated from the original and included in the third volume of the series, published in 2012.

The first thing that stands out is the portrait of John Edwards Holbrook which serves as the frontispiece of the book. This is complemented by a photograph, placed between the two columns of the editor's note, of Daniel Huntington, painter of the portrait, and an unnumbered color plate on page 4, consisting of four additional images of the father of North American herpetology (plus their respective captions). After this Holbrookmania, there are 42 black-and-white, full-page plates, printed on recto and verso of 21 pages, with their own pagination, scattered in the main text. The majority reproduce letters from renowned herpetologists, others show facsimiles of plates or texts of special value, and others illustrate curious, miscellaneous things, like Vaillant's diploma. In all but one case the epigraphs are a delightful source of new information, and this alone is worth the inclusion of this new edition in our libraries. Next, the Index to Biographies was enhanced to include all names from all the volumes in the series, and after that, seven pages of corrections and annotations for volumes 2 and 3 are included, mostly adjusting some dates of birth and/or death, but also including seven previously unpublished portraits and one signature.

The real wonder, however, is at the end of the book, where 54 full-color, full-page plates, numbered from 43 to 96 have been added. The selection is exquisite and the captions, as usual, very enriching. The entirety, including the 42 black-and-white plates and the additional portraits and signatures, constitutes a kind of *Thesaurus* of Adler's magnificent collection and library.

If I may digress, not long ago, while re-reading Schneider's (1799) *Historiae Amphibiorum*, I was struck by a comment of this German author that referred to the plates of "our lizards" drawn by Roesel von Rosenhof, and shown to him by his friend, Iohann Hermann. In his words, "... Learned men should pray that these plates, along with their annotations, will be published by public subscription, or by the desire of a bookseller who wanted to invest the money, not only because the genius of Roesel deserves public praise, but also because they will greatly increase our knowledge of lizards, those four-legged animals whose history other wise men and scholars already learned to admire ...." Plate 45 in Adler's new edition is palpable evidence that Schneider's desire remains valid more than two hundred years later.

A few paragraphs above I suggested that information related to one plate had a problem. This is the comment on plate 2, illustrating an individual of the Emerald Tree Boa from Surinam, taken from Linnaeus' (1754) description of the collection of the Swedish King, Adolf Frederick. Adler mentions that the specimen was collected by Daniel Rolander, and this is not so. It is true that Rolander commented on that snake under the name *Cenchris viridis*; in his words, "... a snake of large bulk, had climbed some tall trees in several places. Its head more often than not looked down. Its open jaws reveal a capacious circumference. It's said to swallow down small deer, squirrels, rabbits, small anteaters, mice and opossums. It looks like the trunks, branches and leaves of trees. And so, walking through the forest, as you touch a tree trunk, you sometimes encounter this snake at the same time. It is extremely cold, as all amphibians, and causes a chill in

whoever touches it ....” But it is also true that Rolander arrived in Surinam on June 20, 1755 (old style), and the observation on the snake was on August 1 (Rolander 2008). It is probable that Linnaeus’ (1758) comment on *Boa canina*, attributed to Rolander (the snake was “adored by the Americans”) misled Adler. An old adage says that perfection is restricted to the gods, and this misinterpretation does not alter the quality of the work.

Before concluding, I want to ask a rhetorical question. In times in which we care so much about the latest innovations, to the point that many journals make available pre-publications of their will-be articles in electronic format, is it not anachronistic not only to edit, but to re-edit a volume on the history of herpetology?

The short answer is no, it is neither an anachronism nor wasteful, although this may be considered just a matter of my personal preferences. The long answer was probably given, in the twelfth century, by John of Salisbury in his *Metalogicus* (circa 1130; see Joannis Saresberiensis 1848), when he wrote: “...Bernard of Chartres used to say that we were like dwarfs seated on the shoulders of giants. If we see more and further than they, it is not due to our own clear eyes or tall bodies, but because we are raised on high and upborne by their gigantic bigness....” The phrase has become a cliché, but the virtue of common phrases is that they frequently are tested truths (something unthinkable in science). Furthermore, since the advent of the rules of nomenclature, the past is present in all our studies. This is so because the Codes of Nomenclature, due to the inclusion of the principle of priority, are the only set of “laws,” at least that I know, that have retroactive application. Consequently, whenever we want to step forward in taxonomic studies, we must look back to 1758 and beyond. And that “beyond” goes back to the first printed description of an amphibian or reptile because, at least in zoology, although the names prior to 1758 are not valid, their content may form part of the definition of the species of which they are synonyms.

But, what is the real value of this book (and of the whole series)? Reading this first volume of compiled biographies, portraits, and signatures of 152 herpetologists, from Conrad Gessner to Avelino Barrio, is almost like spying through a keyhole (an increasingly difficult thing because fewer locks have a hole), on the how, when, where, why, and what of some of those who preceded us in order to better understand and interpret their work. These include women and men who were aristocrats who led an almost dilettante life—with amphibians and reptiles as a hobby, clergy and soldiers, peripatetic exiles who changed countries every few years, and others who never moved from their own neighborhoods; those who died young, those who reached old age, and even someone who, while waiting for a ride to the museum, was surprised by the first nuclear attack. All of which reminds me of Foucault’s (1977) concept of genealogy, of which the French philosopher wrote “...Genealogy (...) requires patience and a knowledge of details and it depends on a vast accumulation of source material. Its ‘cyclopean monuments’ are constructed from ‘discreet and apparently insignificant truths’ and according to a rigorous method (...). In short, genealogy demands relentless erudition...” This book illustrates this well.

e-mail: cesarlba@yahoo.com

I have always been a fan of herpetology books. I enjoy reading them carefully and evaluating and critiquing their content, often in the pages of *Herpetological Review*. Only a few times in my experience have I found a book that is a jewel… an impeccable book (because such thing as a perfect book does not exist)—a book that inspires and reminds you why you are drawn to herpetology in the first place. This book has clear but entertaining text, excellent images, and exquisite design. In other words, it is a masterpiece!

The book is the work of three young friends whose careers I have followed since the beginning. Two of them, Alejandro Arteaga and Lucas Bustamante, are still in their early 20s. I have had the great fortune to be with them in the field and to see the efficiency with which they work. It is a pleasure to see their work come to fruition in this book about a herpetological community in the cloud forests of Mindo, in western Ecuador.

The book cover is an attractive compilation of images of reptiles and amphibians of Mindo, all on a white background. This is a common presentation for all photographs in the book. The authors, who are known as superb herp photographers, have chosen, for mostly taxonomic reasons, to illustrate every species on a white background, avoiding the distraction of other elements, and focusing the reader on the subject of the account.

The book starts with a foreword by Jonathan Losos, a well-known herpetologist from the Museum of Comparative Zoology at Harvard. Alejandro Arteaga, the first author, follows with a preface explaining the motivation behind the book. The acknowledgments are worthy of note as they are presented on a beautifully designed page (p. 7) with the name of each colleague appearing at a size proportionate to the importance of his or her contribution. Following this is the Introduction, including some tips for herping in Mindo (usable throughout the tropics), and how to identify herps. This is facilitated by illustrations showing the salient features of amphibians (fig. 2), the groin pattern in rainfrogs (fig. 3), the principal scale types of lizards (fig. 4), the dewlap coloration of anoles (fig. 5), and the basic terminology for snake scalation (fig. 6). An explanation about the plan and use of the book is found afterwards.

Each species account includes several paragraphs as follows: recognition of the species (size, coloration, characteristic features), natural history, local and general distribution, conservation status, etymology (they make an extraordinary effort to show the origin and meaning of the scientific names, which I deeply appreciate and enjoy), and when significant, taxonomic notes. This is the only book I know where each account has been so carefully cone that all reviewers that contributed by commenting or correcting are named (superfluous perhaps, but an indication of the care taken by the authors). Lastly all references are cited in order of appearance through the text, where they are numbered.

The description of coloration deserves explanation. The authors decided to use a palette of colors like that used by a painter. Descriptions of coloration are commonly so subjective that a purplish green can be also greenish fuchsia depending on the eye and the experience of the descriptor. To avoid this, they present a visual reference showing the amount of variation in their "painter's palette," which I see quite useful.

A short but well-informed section is devoted to the study area, putting Mindo and its surroundings on the map, and commenting about its touristic importance.

101 species of herps are included in this book. First are amphibians. The first photo, one of *Atelopus longirostris*, a species considered extinct, looks somewhat strange. Alejandro Arteaga explained that it was a preserved individual, for which the eye was digitally manipulated to give a more life-like appearance. Illustrations, all exquisite, of extinct or critically endangered amphibian species (*Atelopus mindoensis*, *Rhaebo caerulostictus*, *Cochranella balionota, Strabomantis helonotus, S. necerus, Hyloxalus lehmanni, Gastrotheca guehtheri*) were made by Rita Hidalgo or Silvia Cevallos.

Some interesting new information is embedded in the accounts. About *Epipedobates darwinwallacei*, there are two interesting points. One is that the females are the ones carrying the tapoles (which has only been reported in *E. anthonyi* and *E. tricolor*, Lötters et al. 2007), but the authors do not give any reference about this. The second is that the tadpoles are cannibalistic! The reference is the field notes of Alejandro Arteaga. As it is an interesting rarity within Dendrobatidae (only corroborated for *Dendrobates* (*Ranitomeya*) *imitator* and *D.* (*R.*) *variabilis*; J. C. Santos, pers. comm.), this aspect should be further commented on or better explained.

I really like plates with several individuals depicting the intraspecific variation, like that for *Pristimantis hectus*. However, the authors do not comment if the individuals are depicted at the same scale. The same applies on page 152 for a composite plate of the snake *Atractus dunni*.

Among the reptiles, the authors state that *Basiliscus galeritus* is omnivorous, feeding on invertebrates, fishes, seeds, and fruits. I observed a subadult basilisk in Itapoa, Esmeraldas Province, preying upon and almost swallowing an adult *Pristimantis* sp., suggesting an even broader diet. For a few figures the captions are incomplete, as on page 129: "Adult *Anadia rhombifera* from" (locality lacking). This also happens on page 137 for *Anolis aequatorialis*. Although I appreciate the excellent photography, it seems that in some cases the selected photographs are not sufficient to show the most striking characters of some species. When certain characters are the only ones that can externally distinguish close relatives, those characteristics must be depicted. In the case of *Anolis lyra*, I really wanted to see the "lyre-like" mark on its back of the head; in the case of *Dendrophidion clarkii*, the nuchal collar, which is the only easy character to separate it from *D. graciliverpa*, it is not clearly visible. Also, I would like to see the "anchor-like" mark on the back head of *Micrurus anchoralis* more clearly.

The authors do not use the family Dipsadidae, despite its proven evolutionary value (Zaher et al. 2009; Pyron et al. 2013). The distribution of *Erythrolamprus epinephelus* also includes Costa Rica, which is not included in the distribution section. However, many authors are clear that subspecies of this highly polychromatic species deserve full species status, and thus, Costa Rican and Ecuadorian *epinephellus* would be different species (*juvenalis* for Costa Rica and *albiventris* for western Ecuador; Dixon 1983). That last comment applies for many amphibians and reptiles.

With the snake *Saphenophis boursieri*, I could not see the white postocular stripe mentioned in the Recognition section for the depicted specimen, but rather a black one! The white I see is a labial bar continuing to the throat (all spotted with black). There is no mention of ventral patterning (except for the photographs that illustrate the throat and tail). I do not personally know this snake and thus, I cannot be sure if the specimen photographed is aberrant, or if the text is misleading. The *Tantilla* "*melanocephala*" depicted is indeed very different from those I have seen in other Neotropical countries, and, as the authors comment wisely, surely a species complex. When representing *Urotheca lateristriga*, a small and harmless snake, the authors say that they are rarely fatal to humans. This means that even in rare cases, there are deaths due to this snake. Such assertions should be further discussed or at least referred to some authoritative paper.

The maps constitute a real plus for this book. Not only are they neatly prepared, but they also include all localities known and the potential area of distribution is illustrated for species represented by more than 10 localities. However, being a book

about Mindo, a very discrete area, I believe in a future edition the authors can add a local map, like the one on page 28, with precise localities for all species. In the distribution section, however, they mention all known localities in Mindo where the species have been seen.

I usually do not deal with common names, but I am trying to advocate for a change in them. It has been very popular to call the Terrarana "rainfrogs." However, terraranans are direct developers and breed on land and often vocalize when there is no rain. The straight translation of Terrarana is landfrog, and they should be called by this common name (Barrio-Amorós et al. 2013). To choose common names can be tricky and in some cases there are odd results. For example, I would like to know why *Pristimantis laticlavius* is called in English "Bacon Rainfrog." Is it tasty? Another strange common name is the "Spring Rainfrog"—why Spring? There is no such discrete season in the tropics. This problem also occurs in Spanish. If the authors call *Pristimantis nyctophyllax* "Cutín celador," what vernacular name would they apply to *Pristimantis celator*? If new common names are coined by the authors, they should explain them in the etymology section. I do acknowledge, however, the difficulty of selecting useful common names for animals that are rarely going to be referred to by non-specialists. I did it too in my work on Venezuelan amphibians (Barrio-Amorós 1998) and it was a nightmare!

Something I have not seen before is the synergy of an internet web page (www.tropicalherping.com) with the book itself. There are complementary data, like the recorded calls of 33 species of amphibians that are shown on the web under each species account.

Despite all the positives, I also have a few complaints. Figure 1 is a schematic habitat drawing with various microhabitats indicated by small letters. In order to determine which species occur in which microhabitats one must scan down a list of more than 100 taxon names. This is cumbersome; an alternative might be to number each species and provide a list of numbers corresponding to each microhabitat.

In figure 2, the principal identification features for amphibians are illustrated on a number of different drawings. These could be more effectively combined and illustrated on just one or two stylized frogs. Also, the letter "ñ" is used in figures 1, 2, and 6; this letter does not occur in the English alphabet, and, with small print, resembles "n," which is also used in these figures. In each chapter, the figures start again with number 1, rather than being numbered continuously. This is confusing as there are four figure 1s (five including the one in the addendum describing a new species of *Pristimantis*).

There are some inconsistencies in citations; for example, author names and dates that appear in the text without parentheses; for example: Savage 2002, rather than Savage (2002) or (Savage 2002).

As a herpetology book, *The Amphibians and Reptiles of Mindo* stands out for its beautiful design, white background photography of all 101 species in the area, clear and informative text, and a manageable size and weight. However, it is not usable in the field. A second edition could be improved by printing on waterproof paper. Dichotomous keys and a more in-depth treatment of tadpoles as well as a short chapter dealing with the prevention and treatment of snakebite would also be desirable.

Also, some vital data are missing in my opinion, specifically the type locality of each species. In an area where new species resembling known forms might be expected to be found, this is important to help determine which population represents the described form.

The book includes the description of a new species of landfrog (or rainfrog), *Pristimantis mindo*, in an addendum by Arteaga, Yanez-Muñoz, and Guayasamín. Although I prefer well-known journals for such actions, the presence of this description does not bother me. It has been made with great accuracy; it is very detailed, based on a suitable number of specimens, appropriate comparison with similar species, bioacustic and genetic data. The only minor detail that the authors seem to forget is to give common Spanish and English names, to be consistent with the rest of the book.

I like the efficient use of technical words. This could be a little off-putting to non-specialist readers, but there is a glossary at the end of the book to solve this potential issue. However, not all terms appear at the glossary (e.g., scutcheon, holocrine, cathemeral, cryophobic, molluscivorous, lumbricophagous, etc.). The glossary is followed by an impressive list of 1935 references—one of the most complete I have seen for a small book like this. Finally, the last pages introduce the authors in a humorous way, complete with their "scientific names" and funny photographs.

With the kind of data presented in this book, the general area of Mindo, a great touristic attraction for those looking for adventurous activities as well as relaxation (plus one of the best bird watching areas in the world), will be now a top destination for herpers, thanks to the detailed work of the young authors of this book. I only hope a second edition incorporating the potential improvements suggested above will be possible. This book will be a real jewel in any herpetologist's library.

Bioacoustics has long been an interesting field of study for herpetologists. Calls are one of the most characteristic traits of anurans, perceived and used to distinguish species well before the animals themselves are spotted. Although many field herpetologists carry a recorder as a mandatory piece of equipment, the recorded calls of many species are still not available. The *Sound Guide of the Calls of Frogs and Toads from Southern Brazil and Uruguay* compiled and edited by Axel Kwet and Rafael Márquez, advances our knowledge of the anuran calling repertoire.

This guide presents the calls of 109 anurans, although 16 of the species were undescribed and/or uncertain as of 2010 when the guide was published. The calls are divided into two audio-only compact discs: one with 55 species belonging to the family Hylidae, and the other with 54 species belonging to ten additional families. Each species is represented by a single track, generally divided into different cuts with overall good quality recordings. The listener can follow the tracks and their cuts using a color print booklet provided with the audio CDs. The booklet, 56 pages long, contains scientific name (ordered by species group at the genus level), photograph, distribution map, and natural history information for each species. The photographs provided are small, but this is to be expected for a sound guide. The maps are very simple but somewhat confusing because of the recurrent change of scale, but they are still a nice addition for this type of publication.

The level of detail for the calls is noteworthy. First of all, more than one cut is presented for most species, stating, for example, the social context in which the call was emitted and/or emphasizing when more than one type of note occurs. Thus, even if the call is not sufficiently understood to receive a definitive classification (Toledo et al. 2014), the guide provides a valuable starting point for natural history and behavior studies. Moreover, additional descriptions are given in the audio and/or booklet, for instance, background noise, different species participating in the chorus, air temperature, time of recordings and type of recording filter, factors that may influence the calling activity of frogs and the quality of the recordings.

The accessibility to the text is very convenient. Every piece of information is given in English, Spanish, and Portuguese, which is great for use in undergraduate courses, where students might not be comfortable with the English language, as well as anybody else that may fall into this category. Although there is not an upfront definition of the bioacoustic terms used throughout the booklet, the language is intuitive and accurately utilizes the scientific terminology of this field.

At least four other sound guides for Brazilian species have been published (Atlantic Forest domain: Haddad et al. 2005, Toledo and Haddad 2011; Cerrado, Campo Rupestre, and Pantanal domains: Toledo et al. 2007; Rio Claro Farm, São Paulo state: Maffei and Ubaid 2014), but each of these contain 76 species at most. At the same time, this is the first sound guide for frogs in Uruguay, including over 30 out of 48 known anurans (Maneyro 2012), which is a huge contribution to the field of herpetology in that country. Furthermore, the geographic range of almost 20 species included in the guide extends to northern Brazil, as well as Bolivia, Paraguay and Argentina. The result is a comprehensive overview of frog calls from habitats on the border between Brazil and Uruguay (e.g., coastal dune zone and grassland; Maneyro and Kwet 2008), and also from a variety of habitats throughout Brazil, Uruguay, and additional countries.

Although some open access websites make frog calls available (e.g., AmphibiaWeb), the content is usually not as detailed or standardized across researchers. In this guide, in particular, most of the 109 species were recorded by Axel Kwet, which diminishes the recording setting and equipment variation. In conclusion, the *Sound Guide of the Calls of Frogs and Toads from Southern Brazil and Uruguay* is a well-done and welcome project. Because this guide was released in 2010, we believe that within a few years it would be promising to have an updated — and maybe interactive—sound guide, incorporating the resolution of the undescribed and/or uncertain species. This would represent an even more useful contribution to South American herpetology to which the scientific editors Kwet and Márquez are clearly committed.

e-mail: dr.joe.mitchell@gmail.com

Almost everyone now knows that amphibians are in trouble. Some concerned individuals are in positions to stem or even halt declines in the areas in which they work or live. Many simply want to help. However, conservation of amphibians is complicated, many sided, and must be approached from many different angles. People involved in the movement, especially those not trained in conservation biology, need guidance to help them solve their specific problems and meet their goals. This book joins the procession of books and documents offering practical information that can direct positive actions on the ground.

The authors of this book used an evidence-based approach to aid biodiversity conservation. This approach uses current best evidence to make decisions about, in this case, amphibian conservation. The umbrella organization is the Centre for Evidence-based Conservation (CEBC, www.cebc.bangor.ac.uk) in the United Kingdom. CEBC is a source of advice on evidence-based practices and coordinates the Collaboration for Environmental Evidence program. Program staff help others to undertake systematic reviews on issues of concern to policy and practice in a variety of fields. Systematic reviews of specific conservation interventions that have had proven benefits are their primary tools to support projects that rely on the decision-making process. "Intervention" appears to mean actions taken to thwart a particular type of threat (e.g., agriculture). It is equivalent to "management guidelines" in the Habitat Management Guidelines (HMGs) series produced by Partners in Amphibian and Reptile Conservation (PARC, www.parcplace.org), a conservation NGO based in the United States. This book is a synopsis of the result of a global search of the amphibian conservation literature, including dissertations, theses and available gray literature.

This small book (234 x 156 mm) is one in a series entitled *Synopses of Conservation Evidence* produced by the CEBC. Others have been published on bee, bird, farmland, and bat conservation. The authors of this book summarize evidence relevant to the practical conservation of amphibians to provide a global list of interventions that could benefit amphibians (from the information page that accompanied the review copy). They claim the book is a thorough summary of what is known, or not known, about the effectiveness of amphibian conservation actions across the world. The target audience includes land managers, conservationists in the public or private sector, farmers, campaigners, consultants, policymakers, and researchers and land owners seeking to protect local wildlife. The book is based on scientific conservation literature derived from complete series of 18 herpetology journals (but not *Herpetological Review*), 30 conservation journals, and web searches using ISI Web of Science and Google Scholar. To be included, the paper must report an intervention actually applied in the field and subsequently monitored quantitatively. The authors found 416 studies that met these criteria.

The book's outline and chapter titles are based on the International Union for the Conservation of Nature (IUCN) Unified Classification of Direct Threats (www.iucnredlist.org/technical-documents/classification-schemes/threats-classification-scheme). However, understanding the book's organization requires some effort. Each of the first ten chapters focuses on a particular threat (e.g., transportation and service corridors, pollution, climate change and severe weather). These are followed by four chapters with general headings (e.g., Habitat protection, Species management). A shaded box that begins each chapter includes a brief statement about the threat and where it is addressed in other chapters. A list of "Key messages" (= interventions) follows with a single sentence or a paragraph that briefly summarizes results of the literature search. These messages (interventions) then form the titles of a series of individually-numbered sections with their own bulleted summaries followed by a background box and a single paragraph or several pages of text. Boxes and text sections that include references to particular papers are followed by their own literature cited list. Each paragraph in the text section summarizes information in one published paper. The information in these paragraphs includes methods and numeric results but no conclusions or how the reader should interpret the results. Each paragraph starts with phrases such as "A before and after study… found that", "A review … found that", and "A controlled, before and after study … found that." Not much writing creativity here. The last four chapters based on IUCN Classification of Conservation Actions start out as just described, but additional text is added on anurans and/or salamanders, as well as selected, mostly European, species. Paragraphs summarizing each study in these sections are structured as above.

Some of the chapters contain extensive text and numerous citations. Others contain no useful information. For example, Chapter 6 on the threat of human intrusions and disturbance has one preselected intervention: "Use signs and access restrictions to reduce disturbance" and a sentence noting they found no literature-based evidence on this topic. The intervention and the note in Key messages are repeated verbatim in the section just below it. The authors would claim that including topics lacking literature is useful. But why is there only one intervention and why this one? There are many other ways humans intrude on amphibian habitats that could have been included. Several management guidelines in the PARC HMGs would have nested nicely in this chapter. However, I assume they did not use the HMGs because as yet no publications include results of monitoring studies.

Chapter 3 on the "Energy production and mining" threat contains a single intervention that fits one species in a restricted location. The Kihansi Spray Toad (*Nectophrynoides asperginis*) in Tanzania is critically endangered from loss of habitat below a hydroelectric dam that blocked the montane stream and eliminated 90% of the spray zone. The authors cite one before-and-after study that describes the effectiveness of a sprinkler system installed to aid the toad's recovery. The single intervention included in this chapter, "Artificially mist habitat to keep it damp," might be appropriate in this and perhaps a few other similar locations, but it is not useful to a global audience as implied.

The lack of information on how to apply the interventions and information in this book to conservation issues in specific habitats weakens the book's usefulness. The authors do note the synopsis is not intended "to make decisions for you" but provide support for those decisions. But how can land managers, land owners, and others in their list of target audiences interpret the information in this book for their conservation projects without guidance from professional conservation biologists or ecologists? For this reason the book's usefulness will be limited to those who understand the science and are able to interpret the interventions for on-the-ground actions.

Several minor points should be mentioned. Chapter 5 (Threat: Biological resource use) was omitted from the review copy, and even from the Table of Contents, but this was apparently a printing error and has been rectified in copies subsequently distributed. No reviewers were acknowledged. Some of the writing would have benefited substantially from their edits. There is no summary or conclusions chapter. The pricing structure seems unusual. Why would anyone buy the hardback version of this book for US $114.99 when he could have an electronic version for US $16.99? The paperback version is more affordable, but in my view is still overpriced for what you get. One can also download individual interventions on a searchable database (www.conservationevidence.com), apparently for free.

The practical interventions and associated background literature are useful contributions to conservation and management efforts on behalf of amphibians. I found many publications of which I was not aware. The authors deserve credit for conducting the extensive literature search and providing summaries within the intervention (management guidelines) context. Unhappily, as Roger Conant would say, they fell short of their goal to provide information readily understood by a broad audience. I would recommend this book to practicing conservation biologists but not to consultants (unless well trained), campaigners, farmers, land managers, policymakers, or private land owners.

The Biology of Chameleons

Krystal A. Tolley and Anthony Herrel (eds.). 2014. University of California Press, Berkeley and Los Angeles, California, USA, and London, United Kingdom (www.ucpress.edu). xii + 275 pp. Hardcover. US $65.00. ISBN 978-0-520-27605-5.

WOLFGANG BÖHME
Herpetology Section, Zoologisches Forschungsmuseum Alexander Koenig, Adenauerallee 160, D-53113 Bonn, Germany
e-mail: w.boehme@zfmk.de

The content of this book exceeds its title remarkably. *The Biology of Chameleons and its Morphological, Physiological, Paleontological and Evolutionary Basis*, though cumbersome, might be more appropriate. The book comprises 10 chapters written by authors who are well respected in their special fields. The subjects of these chapters, apart from the introductory one, are: (2) anatomy, (3) physiology, (4) function and adaptation, (5) ecology and life history, (6) sensory systems and communication, (7) evolution and biogeography, (8) systematics, (9) fossil history and (10) conservation—truly a wide array of topics!

Chapter 1, written by the two editors, is a mere introduction to the following chapters, but the great fascination Krystal Tolley and Anthony Herrel have for chameleons is clearly discernable. The first and overall impression of this book is certainly excellent, and the list of contents looks absolutely complete. However, some comments may nonetheless be warranted. These concern some suggestions on what has been overlooked, mainly in respect to certain literature references which I regard to be important, and thoughts and interpretations on some aspects which, in my view, have not been fully discussed or synthesized.

An example of a missing reference concerns the paragraphs *Microstructure* (p. 39) and *Ear* (p. 45) in Chapter 2. A very recent detailed study by Marlene Spinner (Spinner et al. 2013) if already available to the editors (they did cite other papers from 2013), would have been a useful addition. Another matter of citation is the correct information that the apical structures of chameleonid hemipenes may vary not only ontogenetically but also seasonally (p. 54). This is credited to Klaver and Böhme (1986), however, it was first mentioned and documented by Böhme (1988), a title not cited in the book.

An example of the second point is seen in the paragraph about the *Ear*. Here, I find no mention of the "Cranoliti" (calcified endolymphatic sacs in the otic region) described in detail by Siebenrock (1893) for *Brookesia superciliaris*. These were described in the same paper as the uniquely derived structure of the vertebral column, which Siebenrock stated would only be understood when the biology of this chameleon was better known. In the meantime, we have had the opportunity to learn much more about the biology of *Brookesia*, one aspect of which, "freeze and roll" antipredator behavior, is discussed in Chapter 6 (p. 127) of the present book. However, a direct link between the endolymphatic system, the aberrant vertebral structure and this behavior in *B. superciliaris* has not been made. As has been argued in an earlier paper (Böhme 1982), the "Cranoliti" seem to function as a static organ, since calcified endolymphatic sacs are restricted to lizards with a climbing life style (Kluge 1967; Moody 1980). In *Brookesia*, a cataleptic antipredator mechanism (freeze and roll) should be directed against visually—rather than olfactorially-oriented enemies, i.e., against birds with strong visual accommodation capabilities rather than against scent-sensitive carnivorous mammals or even tongue-flicking snakes. So, when a prey item such as a *Brookesia* abruptly stops moving and thus disappears from the bird's visual field, the predator will well try to check with some pecks whether the now motionless object is edible or not. And here, the double-protected vertebral column of *Brookesia* can be life-saving only if the chameleon orients this heavily ossified backbone, and not the vulnerable flanks or belly, towards the predator. That the calcified endolymphatic system can actually work as a static organ in the context of the cataleptic freezing behavior, was corroborated by Schmidt et al. (1989) in both wild and captive *Brookesia*. When grasped by a bird bill, many *Brookesia* species exhibit a high-frequency body vibration which is likely to affect a bird, with its pneumatisized skull bones, more than other potential predators (Böhme 1982). In the book by Tolley and Herrel (p. 112), the generalist feeder *Brachypteracias leptosomus* is listed as a bird that searches the leaf litter for *Brookesia*. This species would be the ideal candidate for an experimental *in situ* test of the above hypothesis.

The short paragraph on "Sexual dimorphism: body size and ornamentation" (p. 126) also misses some interesting correlations. It is only stated that sexual size dimorphism (SSD) is either female-biased or male-biased, and ornamentation is dealt with separately. However, there is a clear interconnection between male-biased SSD and head ornamentation in that males in species with head ornamentation are markedly larger than in those without such ornamentation. The best examples are the horned species of *Trioceros* in Africa, where the adorned males are always considerably bigger than the corresponding females. Within the Cameroon radiation of *Trioceros*, in the so-called *T. cristatus* group, in the horned species *T. quadricornis, T. montium,* and *T. pfefferi,* the male grows much larger than the female, but the opposite is true in the hornless *T. cristatus* in which the female grows much bigger than the male (for data see Klaver and Böhme 1992). The same is true for the East African horned species. The same principle also applies in the genus *Chamaeleo* where horns are functionally replaced by an extremely high casque in, for example, *C. calyptratus* males, which are much larger than conspecific females. Conversely, in casqueless species of the *C. dilepis* complex, most extremely in *C. roperi*, adult males are really dwarfs in respect to females. An even more comprehensive correlation between ornamentation and hemipenial structure has been discovered: species with ornamented males tend to have similar hemipenes while those resembling each other in external morphologically, show deep divergences in hemipenial structure (Ziegler and Böhme 1997, fig. 113). This means that female choice depends on the external form of males (i.e., a pre-mating signal) in the first case, but on hemipenial structures in the other.

This aspect leads directly to the question brought up on page 130, viz., "whether the degree of different visual signals (coloration, ornamentation, and behavior) among closely related species is positively related to the number of sympatric species." Here, the paper by Rand (1961) should have been cited, since it already demonstrated that there is no sympatry (or more precisely, no syntopy) of chameleon species in East Africa with identical head ornamentation (in this case, three horns). Likewise, Parcher (1974) demonstrated experimentally in Madagascar that males with head ornamentations artificially removed are no longer recognized as conspecific by their respective females. In another study it was shown that in cases of emerging syntopy, males of a horned species will reduce their horns when a second horned species expands into its range and habitat; this character displacement can be demonstrated to have occurred in a sequential fashion, due to historical climate change (Böhme and Klaver 1981).

My next remark concerns the chapter on systematics. The listing of species in the generic arrangement follows the most recent revisions, it is, however, not always consistent. As an example, *Trioceros eisentrauti* is still listed on Table 7.1 as a valid species, but is missing in the enumeration of *Trioceros* species on p. 171, obviously because it was downgraded to a subspecies of *T. quadricornis* by Barej et al. (2010). Here it becomes clear that it was disadvantageous to leave all subspecific taxa out, because the current checklists (Mertens 1966; Klaver and Böhme 1997) demonstrate how many taxa originally described as subspecies subsequently received full specific rank. This also concerns the taxon *quilensis* Bocage, left out in this book obviously because the editors regard it as conspecific with *C. dilepis*. That it has a hemipenial ornamentation dramatically different from that of *C. dilepis* has been demonstrated by Ullenbruch et al. (2007). This may also have relevance for the color figures 1.3 and 8.5, which show the same individual of "*Chamaeleo dilepis*." However, due to its small rudimentary neck flaps, this specimen is certainly not true *C. dilepis*, but rather—if South African (the locality is not mentioned)—*C. quilensis*, underlining my statement above.

I should like to add here that the etymology given for the name *Chamaeleo* (or *Chamaeleon,* respectively) as derived from ancient Greek and meaning "ground lion" does not gain more sense and probability by repeating it again. Rather, the alternative etymological derivation from the old Semitic word "gamal" (camel) with the diminutive ending "-ún," i.e., "gamalún"—little camel by Keller (1913) should also be considered. The dorsal hump of resting chameleons (see, for example, figs. 8.4. and 8.5. in the present book) indeed resembles a little camel much more than a terrestrial lion (Keller 1913; Böhme 2011), although the Greek "chamai" may also mean "dwarf" or "dwarfish" instead of "on the ground."

Finally, just a few comments on the list of references. It is clear that the great majority of titles of this rather complete bibliography are in English, but is inconsistent in respect to other languages cited. In several German, French, Spanish, Portuguese, etc. titles the name of the respective language is added in parentheses, but in others not; I regard this as unnecessary because it is self-explanatory when reading the title itself. Some references missing in this list and, in my view worthy of being cited, have already been discussed above. In some citations the titles are incorrectly reproduced, in other instances the journal names have errors. For instance Moody's (1980) thesis is cited as "The phylogenetic relationships of taxa within the lizard family Agamidae" but the correct title is "Phylogenetic and historical biogeographical relationships of the genera in the family Agamidae." Parcher (1974), is said to have been published in "Zeitschrift für Tierzuchtung und Zuchtungsbiologie (sic!)" (a journal for breeders of domestic animals!) instead of "Zeitschrift für Tierpsychologie" which is the famous forerunner of "Ethology," where it actually appeared (although the volume number and pages are correct). Klaver, C. and Klaver, C.J.J. are treated as two different authors in this list although they refer of course to the same person who, according to the acknowledgments, together with Bill Branch reviewed the systematics chapter of this book.

Despite these small corrections, amendments, and additions, the present book by Tolley and Herrel is a great achievement in chameleonology. It will certainly have a great influence on future research on these fascinating creatures, and it will be nice if my comments above on some evolutionary aspects will also stimulate some further discussion.

Art in Herpetology

As space and available material permit, we will occasionally publish examples of historical as well as contemporary herpetological art. We welcome the submission of historical material under the following conditions:

- The work should be copyright-free and be provided as a high-resolution digitized file (consult Herpetological Art and Illustration Coordinator or Editor for specifications).
- Accompanying text should provide information on the subject matter, artist/illustrator, and publication source. Include references as needed to appropriately attribute information from other sources.

Contemporary artists are invited to submit their own work for publication:

- Artist will retain copyright of all submitted material.
- Accompanying text should provide information about technique, media, or other information likely to be of interest, especially to other artists. Other details of interest include the source of illustration subject (e.g., scientific name, geographic origin, etc.) or the work (e.g., book publication, etc.) for which the illustration was produced.
- Artists are welcome to include contact information (e.g., email address, website location), as well as indicating whether original art or prints are available for sale or if the artist is available for commissioned work.

Material may be submitted for review to Jackson Shedd, Herpetological Art and Illustration Coordinator at jackson_shedd@sbcglobal.net.

Studies on Non-venomous Colubrid Snakes and a Few Other Families in Zoos and Aquariums

> So general is the repugnance of mankind to the animals composing these classes, that their study has been overlooked, and they have usually been considered as beings which it was not only necessary but meritorious to destroy. A part of this vulgar prejudice is derived from education, and perhaps some of it may originate from the fact that several of them are furnished with venomous fangs, capable of causing intolerable sufferings and death. To the naturalist and physiologist, however; to those who study nature through her various modification of form and structure, they present some of the most interesting objects of contemplation. Their utility, either in diminishing various noxious animals, or in furnishing food themselves to others, has been lost sight of; and because they were cold to the touch, with a naked slimy skin without hair or feathers, they have been considered as loathsome and hideous, although their structure displays as much of the omnipotence and care of the Creator as can be seen in those which are considered to be the most gorgeous and beautiful of his animated beings.
>
> *Zoology of New-York or the New-York Fauna, Part III. Reptiles and Amphibia.* by James E. DeKay, 1842

This article is last in a four-part series on the history of snakes kept in zoos and aquariums. In each article, I focus on taxa that have been regularly displayed in zoos and aquariums. Certainly there are many other species that have been kept but in generally limited numbers. I would be remiss if I did not acknowledge the enormous contributions of our academic and museum colleagues over many centuries. Without their inspiration, guidance and assistance, we would not know what to call our animals or how these creatures live and die in the wild. Without knowing these facts, we would have been virtually helpless in maintaining them in captivity. Starting with lavishly illustrated books, cabinets of curiosities and operating theaters of anatomy, luminaries like Albertus Seba, Frederik Ruysch, Oleus Worm, Adam Oleareus, Konrad Gessner, and a host of others showed us the beauty and complexity of our natural world (Figs. 1, 2). Many biologists today have not had an opportunity to see these magnificent works of art and this is why I have included them in my articles.

Considerable advances on properly keeping and reproducing herps have been made by herpetoculturists in the private sector (Murphy and McCloud 2010a, b). Compare the behavioral observations in the first published herpetocultural book by Johann Matthäus (or Matthaeus) Bechstein in 1797 on captive care of reptiles (called Amphibians at that time) and amphibians entitled *Naturgeschichte; oder, Anleitung zur Kenntniss und Wartung der Säugethiere, Amphibien, Fische, Insecten und Würmer, welche man in der Stube halten kann [Natural History or Guide to Knowledge and Care of Mammals, Amphibians, Fishes, Insects and Worms which can be kept at Home]*. In it, he covered the European Grass Snake (*Coluber Natrix*, now *Natrix natrix;* Fig. 3) and here are a few quotes from that tome: "*Positive*

COURTESY OF SMITHSONIAN INSTITUTION LIBRARIES, WASHINGTON, DC

Fig. 1. Upon death, zoo specimens should be cosmetically necropsied (if a necropsy is necessary), preserved, and placed in a scientific depository. Those lacking locality data can be used as study specimens. Illustration of cabinet of curiosities from Levinus Vincent's collection in 1704. In the 1660s, Robert Boyle published an article in *Philosophical Transactions* where he described using alcohol for fixing and preserving animal specimens. This important discovery revolutionized herpetological descriptions, for herpetologists and artists were able to scrutinize preserved materials and create detailed diagnostic drawings.

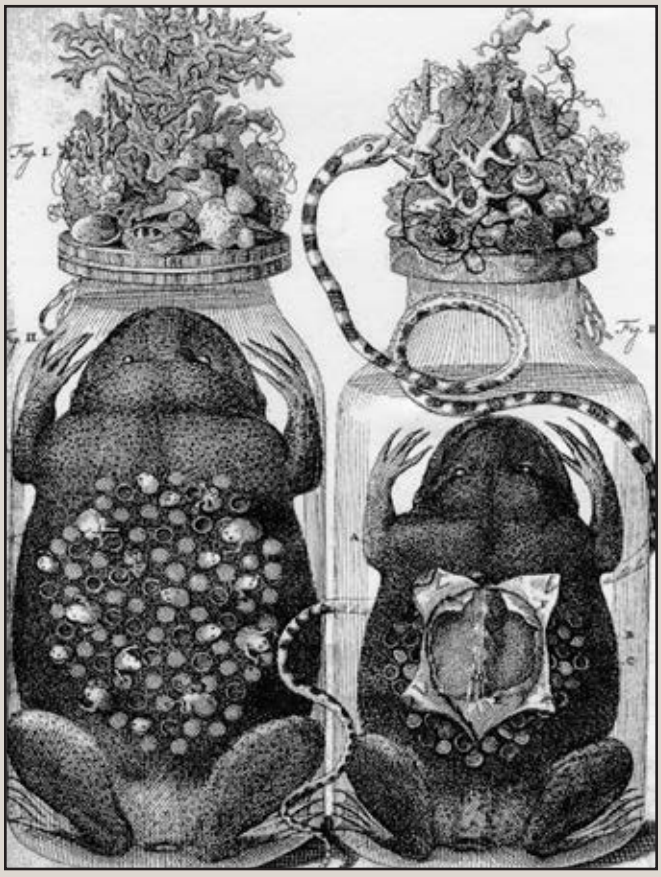

FIG. 2. Snake seems to be Dipsadidae, given New World *Pipa* in the jars. Could be a *Leptodeira* or (very skinny) *Imantodes* based on eating frogs, but is it attacking more diverse prey, including mollusks? Harry Greene suggests that it might be a composite dipsadid. Illustration from Frederik Ruysch's book on a natural history cabinet in 1710—*Frederici Ruischii ... Thesaurus animalium primus = / Het eerste cabinet der dieren / van Frederick Ruysch* ... Imprint: Amstelædami, apud J. Wolters.

Properties—These are certainly endearing animals which can be trained to dance with a stick and the pipe, and to play dead…My friend Mr D. Vognetz has a ringed snake which is so tame that she crawls up and down in the room like a domestic bird, often climbs up on him, crawling up the arms and into the bosom. But it does not easily approach anyone else. He puts it in his pocket, goes into the garden with it and as soon as he emits a loud whistle, similar to the tone with which at mating time they call their mates, it comes to him, crawls up on him, lets him put it in his pocket and remains there without moving until he takes it out again. Since these crawling amphibians often grow exceptionally large, this has provided opportunity for all kinds of fables." (translated from German in Heichler and Murphy 2004).

When I started in the zoo profession in the mid-1960s, I never imagined seeing the amazing numbers of amphibians and reptiles produced by the private community in the following decades. There are several pictures of enormous displays of these animals (Rieck et al. 2001). See Barker and Barker (2014) for a thorough discussion of the topic of the value of animals in captivity and the role that serious amateurs can play in conservation.

Where feasible, I have updated scientific names from those used by the authors in their publications, based on Uetz and Hošek (2014). I follow McDiarmid et al. (1999) for family arrangements.

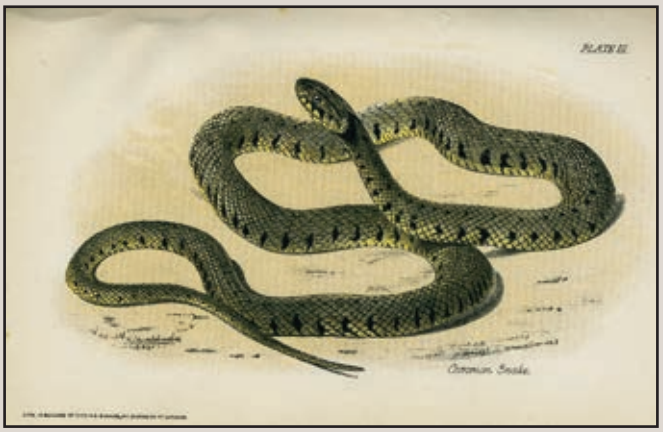

FIG. 3. Common Snake *Tropidonotus natrix* from *Our Reptiles and Batrachians* by M. C. Cooke, 1893. "Everybody shudders at the name of a snake. Very few possess courage enough to attempt staring one out of countenance, or staying to count the number of scales on its head."

TRAVELING THROUGH TIME

As every herpetologist knows, snakes have been the focus of attention of humans for centuries in both positive and negative ways. Brattstrom (1998) postulated that the circular Aesculapian Temple (Tholos) at Epidauros, Greece was likely an early snake pit between 360 and 320 BC. Wajid Ali Shah kept a large menagerie in Calcutta in the 1850s that included tortoises and a large enclosure containing thousands of snakes (Walker 2001). Rulers during this period often kept animals to impress their subjects and competitors. There were many early assemblages of captive snakes, as described in Murphy (2007). One which caught my attention was when Hernando Cortés and his band of soldiers arrived at the Aztec capital Tenochtitlan (now Mexico City) in 1519 and found the Aztec emperor Montezuma's royal menagerie which included snakes. There were over 300 animal keepers so I will remind my herpetological colleagues to continually complain to their bosses about being constantly shorthanded by stressing this factoid. To gain a picture of the relationship of humans and snakes, read Greene (1997), Morris and Morris (1965), and Stutesman (2005).

Arthur E. Brown from Philadelphia Zoo (see Conant 1957) described Marcy's Garter Snake, Trans-Pecos Ratsnake, Gray-banded Kingsnake, Short-tailed Snake, and others (1889, 1890, 1893, 1901a, 1901b, 1902a, 1902b, 1902c, 1903a, 1903b, 1905). Cover and Boyer (1988) bred the endangered and beautiful San Francisco Garter Snake (*Thamnophis sirtalis tetrataenia*) at Dallas and Ft. Worth Zoos. These illegally-collected snakes were confiscated from private persons by the US Fish & Wildlife Service for the purpose of providing captive-born neonates to other zoos to stress the species' precarious state in California and develop assurance colonies. We were told that plans were being considered to clear prime habitat proximal to the airport to be used for additional landing strips and should this become a reality, immediate action for intervention would be needed. The snakes proved to be prolific and many were distributed to institutions throughout the world. In 2005, the Eastern Plains Garter Snake (*Thamnophis radix radix*) reproduced at Cleveland Metroparks Zoo. The same year, the Exiled Garter Snake (*Thamnophis exsul*) produced a litter at San Antonio Zoo. Many years ago, curator Ray Pawley showed me a

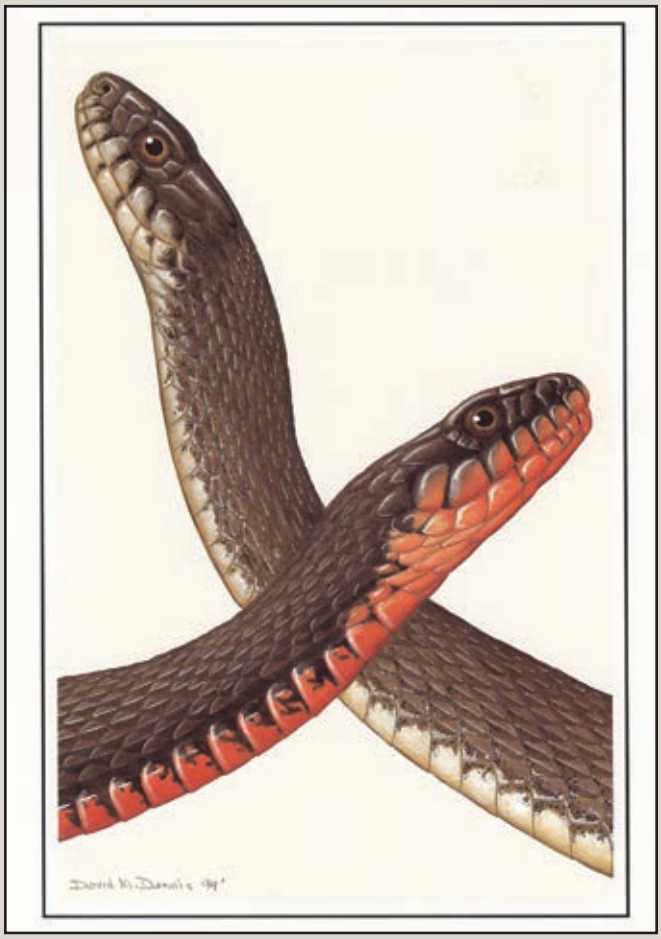

FIG. 4. Two endangered water snakes described by Roger Conant: Northern Copperbelly Water Snake (*Nerodia erythrogaster neglecta*) and Lake Erie Water Snake (*Nerodia sipedon insularum*). Reproduced from a watercolor by David M. Dennis in 1994 from the SSAR book *Captive Management and Conservation of Amphibians and Reptiles.*

FIG. 5. Eastern Garter Snake (*Thamnophis s. sirtalis*) in *The Natural History* by Mark Catesby in 1743.

unique and effective garter snake exhibit at Chicago Zoological Park. The enclosure was filled with human detritus often found strewn in wild areas and vacant lots in the city—rusty tin cans and bed springs, broken shards of glass, discarded food wrappers and newspapers, and junk of all types. Ray's message was simple—we are littering our world with our garbage! North American Queen Snakes (*Regina septemvittata*) produced 48 young between 1872 and 1880 at London Zoo (Coote 2001). Fox et al. (1961) described the morphological effects of low temperatures during the embryonic development of the garter snake, *Thamnophis elegans*. In 1942, Conant reported on young of Brazos Watersnake (*Natrix harteri*) as well as Southern Black Racer (*Coluber constrictor priapus*), and Texas Patchnose Snake (*Salvadora lineata*), and Arid Land Ribbon Snake (*Thamnophis proximus diabolicus*) and Aguanaval Watersnake (*Natrix erythrogaster alta*) (Conant 1965). Lederer (1949) published a lengthy study on the Viperine Snake (*Natrix maura*) and hybrid ratsnakes (Lederer 1950). Reichling (1974) reported upon a new record-size *Natrix erythrogaster flavigaster* x *neglecta*. Petzold bred the Indian Striped Snake (*Amphiesma stolata*) at Tierpark Berlin (Petzold and Stettler 1972) and reported observations on the breeding biology and keeping of *Tretanorhinus variabilis*, a water snake of Cuba (Petzold 1967). Roger Conant was the most prolific researcher on natricine snakes in the zoo community (Conant 1938, 1943a, 1943b, 1945, 1946, 1949, 1950, 1951, 1953, 1958, 1961, 1963, 1965, 1969, 1975; Conant et al. 1945). As a nonagenarian, Roger sent me a copy of his last paper in 2003 on the garter snakes of the *Thamnophis eques* complex from Mexico from data compiled in the 1960s—simply extraordinary productivity. His accomplishments were recognized in an SSAR volume in 1994 (Adler 1994; Fig. 4.) and other publications (Conant 1957, 1980, 1997; Conant and Collins 1991). It bears repeating that Roger was the only herpetologist who returned cloth shipping bags cleaned, pressed, and folded to me (Adler 2004). There are several other excellent references on garter snakes and water snakes (Rossman et al. 1996; Gibbons and Dorcas 2004, Fig. 5).

The late John Werler was director of Houston Zoo for many years (Kawata and Murphy 2004). At Houston Zoo, common Diamondback Watersnakes (*Nerodia rhombifer*) were periodically obtained as living food snakes from a reptile dealer for the King Cobras—they were not frozen until used because Werler felt that the cobras deserved living prey; they were kept in a large enclosure in the rear section. In 1953, Roger Conant described a new taxon in honor of Werler (*Nerodia rhombifer werleri*) from Mexico and a few living ones were collected by him and kept on display to honor John. Just before Conant was to visit, a prankster in the herp department convinced a newly-hired keeper that he had fed all of this very rare subspecies to the cobras by using the ones in the holding enclosure. To continue the ruse, John contacted Roger and they both confronted this terrified keeper for many minutes about his sheer incompetence feeding off these priceless serpents until they both started laughing uproariously and admitted their nefarious deed—the poor keeper had a near-death experience. As an aside, I have collected the nominate form and experiencing them up close and personal is a miserable experience—multiple bites with flowing blood, unpleasant musk, and staggering amounts of metabolic by-products. See Werler and Dixon (2000) for an exhaustive treatment of Texas snakes, including natricines.

Kingsnakes and milksnakes (*Lampropeltis*) have been popular zoo ophidians due to their beauty and hardiness in captivity (Fig. 6). Beginning in the mid-1960s, we began to specialize in this group at Dallas Zoo. We reported on courtship and copulatory behavior in the Mexican Milk Snake (*Lampropeltis triangulum sinaloae*) by looking at three elements—Tactile-Chase, Tactile-

Alignment, and Intromission and Coitus—and by creating this new terminology for a generalized colubrid pattern (Gillingham et al. 1977). Murphy et al. (1978) provided an inventory of reproduction and social behavior in Gray-banded Kingsnakes (*L. alterna*). At San Antonio Zoo, Laszlo (1984) discussed reproduction in captives utilizing environmental parameters. After these snakes were cooled to as low as 9°C in the winter, successful reproduction did occur—in both the Tryon colonies (window left open in unheated room) and the Dallas Zoo group (hibernaculum) (Radcliffe et al. 1974; Murphy et al. 1978; Tryon 1984a). Tryon and Murphy (1982) investigated the reproductive biology of thirteen varieties of kingsnakes (species *mexicana, triangulum,* and *zonata*). Jon Campbell brought some beautiful milksnakes to our Zoo collected from Zapotitlan, Puebla, Mexico, found in desert terrain at 1500 m, and listed in our paper as *L. t.* ssp. Hugh Quinn (1983) later described these as *L. triangulum campbelli.* These snakes proved to be incredibly prolific. Hammack (1989) reproduced the Colombian Milk Snake (*L. t. andesiana*) at Dallas Zoo. Radcliffe and Murphy (1984) described precopulatory and related behaviors in captive kingsnakes and other reptiles. Paul Weldon presented kingsnake secretions to assess the ophiophage defensive response in a large number of crotaline snakes (Weldon and Burghardt 1979). In some cases, the defensive body bowing behavior exhibited by the pitvipers was dramatic as bodies were lifted in an inverted U-configuration with head and tail on the substrate and mid-body pressed to the top of the enclosures. Because it was reported in the literature, we assumed that the pitviper might use body blows directed to the kingsnake swabs but I did not notice this behavior. Later, Chiszar et al. (1993, pers. comm.) felt that this was a strategy used by the pitvipers to wedge themselves tightly into burrows to avoid being seized by the kingsnakes.

When private kingsnake breeders learned about the extent of our collection, many visited the Zoo but often focused only on kingsnakes even though we had a very diverse collection. Some particularly desirable forms which we were reproducing in numbers but were unavailable at that time in the private herpetocultural community were Jaliscan Milksnake (*L. t. arcifera*; these were actually Ruthven's Kingsnake [*L. ruthveni*]; R. Hansen, pers. comm.), Pueblan Milksnake (*L. triangulum campbelli*), and Colombian Milksnake (*L. t. andesiana*). We also had a group of snakes of the *L. mexicana* complex collected by Jon Campbell and Barry Armstrong (see Garstka 1982 for additional information). Fanciers begged us for some neonates but when I explained that zoo policy required that all propagules had to be offered first to AZA members and there was a very long waiting list, a few unscrupulous ones started calling my keepers at home to try and convince me to change my mind by doctoring records to eliminate hatchlings. It reminded me of the tulip craze in Holland during the 1630s. As the private sector became more proficient at breeding kingsnakes, we later decided to move on to other projects and sent most of them to other zoos.

Tryon and Hulsey (1976) noted reproduction in captive Nelson's Kingsnakes (*Lampropeltis triangulum nelsoni*) at Ft. Worth Zoo. At this Zoo, Ronald Markel worked in the herpetological department. He told me that he was planning an ambitious project illustrating as many milksnakes and kingsnakes in color as possible and he succeeded by locating them all at zoos and other places (1990). Herman (1979a, b) bred the Jaliscan Milksnake (*L. t. arcifera*; again, these were actually *L. ruthveni,* as noted above) and Scarlet Kingsnake (*L. t. elapsoides*) at Zoo Atlanta. Kardon (1979) noted breeding in three

Mexican milksnake subspecies (*L. t. polyzona, L. t. nelson,* and *L. t. sinaloae*) at San Antonio Zoo. Korinek (1997) bred Campbell's Milksnake (*L. t. campbelli*) in the terrarium of Olomouc Zoo. In 2004, five Eastern Milksnakes (*L. t. triangulum*) hatched at the Detroit Zoological Institute (Fig. 7). Tryon and Murphy (1982) and Tryon (1984b) described multiple egg clutches in a single reproductive season; this phenomenon is now known to occur in a number of *Lampropeltis* taxa.

Roger Conant (1934) recorded reproduction in the Black Kingsnake (*Lampropeltis getula nigra*) and discussed milksnakes of the Atlantic Coastal Plain (1943a). Hosono (1982) bred the Florida Kingsnake (*L. getula floridana*) at the Kyoto Municipal Zoo in Japan. Mulder et al. (1979) from Audubon Zoo surgically removed retained eggs from a kingsnake (*L. getula*). Tryon and Carl (1980) reproduced the Mole Kingsnake, *L. calligaster rhombomaculata.*

Zweifel (1980) described techniques for maintaining a colony of *L. getula* at the American Museum of Natural History in New York to study inheritance of color pattern. Shaw (1956, 1959) described two-headed California Kingsnakes (*L. g. californiae*) at San Diego Zoo by name: Dudley-Duplex, Dudley-Duplex II, and Nip-and-Tuck. This Zoo has owned several of these snakes over the years and the first one lived over six and one-half years. Boyer and Baldwin (1997) devised a simple method of preventing self-inflicted injury when feeding a dicephalic California Kingsnake by using a collar around one head (pictured in Murphy 2007). Groves (1964) and Groves and Groves (1972) described swallowing of shed skin by *L. getula.*

Ratsnakes are also popular zoo exhibits. I use the term "ratsnakes" in an historical sense, inclusive of both Old and New World representatives that we now know are not closely related (Utiger et al. 2002). Herrmann (1998) reported on husbandry and reproduction in the Black and Yellow Ratsnake (*Spilotes pullatus*) at Cologne Zoo (Fig. 7). At Ft. Worth Zoo, Campbell (1972) bred the Trans-Pecos Ratsnake (*Bogertophis subocularis*) and Tryon (1976) reported on courtship behavior and second-generation reproduction. Brecke et al. (1976) documented reproduction and social behavior in the Baird's Ratsnake (*Pantherophis bairdi*) at Dallas Zoo, and Dathe and Dedekind (1985) at Tierpark Berlin. Tremper (1981) propagated the Neotropical Ratsnake (*Pseudelaphe f. flavirufa*) at Chaffee Zoo. Engelmann (1984) explained egg-laying behavior of the Yellow Ratsnake (*Pantherophis obsoletus*) at Leipzig Zoo. Retired Detroit Zoo curator Jim Langhammer (pers. comm.) had many snakes at Indiana University during our college years including Ludwig, a large female Yellow Ratsnake: "She was about 5 feet long and totally trustworthy around strangers. Ludwig's dimensions were too small to allow her being on the ground among foot traffic but she was often handled by strangers. I often walked Jordan Halls with her settled quietly around my neck. Many strangers would ask directions/questions of me without ever seeing the snake. To my recollection she never struck at anyone. One indication of her gentleness was her intense fondness for large chicken eggs. She ALWAYS began at the blunt end of an egg. If you held it with the blunt end in your palm, she would work to expose that blunt end but never bit the hand in the process. Once engulfed, she would move it down about 10 inches and then crush the egg against her vertebrae before swallowing it further."

Frolov and Kudryavtsev (1985) and Kudryavtsev and Frolov (1984) kept and bred Russian Ratsnakes (*Elaphe s. schrencki*) at Moscow Zoo. Mamet (1989) outlined the reproductive biology of ratsnakes of the *longissima*-complex from Southern Azerbaijan

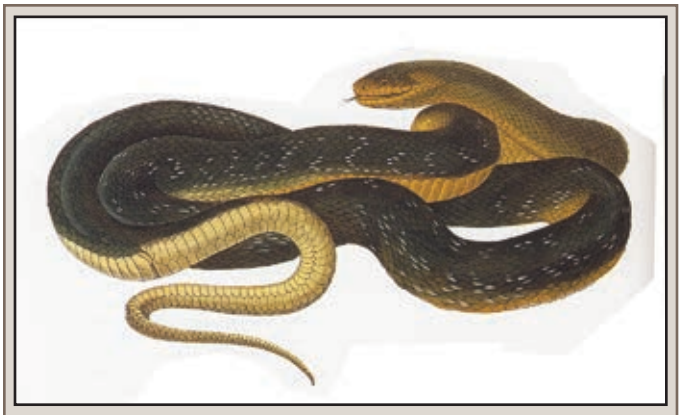

Fig. 8. Baron Georges Cuvier published *Le règne animal…* in 1836–1839. Illustration is Aesculapian Snake *(Elaphe longissima*).

Fig. 9. Yellow and Black Ratsnake (*Spilotes pullatus*) from *Biologia Centrali Americana: Reptilia and Batrachia* in 1885–1902 by Albert Günther. This beautiful and active snake is not often seen in zoo collections.

(Fig. 8). Mamet and Kudryavtsev (1997a) propagated the Mandarin Ratsnake (*E. mandarina*) and Mamet and Kudryavtsev (1997b) provided notes on the reproductive biology of the Asiatic Ratsnake (*Elaphe persica*) at the Moscow Zoo. At Tula Exotarium in Russia, Ryabov (1997) reported upon high productivity in the Radiated Ratsnake (*E. radiata*), natural history, keeping, and breeding the Persian Ratsnake (*E. persica*) (2001), and Ryabov and Popovskaya (2000) provided some comparative data on the breeding of four subspecies of the Stripe-tailed Ratsnake (*Elaphe taeniura*). "This is from Stan Grumbeck who told me that Moellendorf's Ratsnakes (*Orthriophis moellendorffi*) are notably different than the norm in that their eggs feel much more like turtle eggs and that the young do not slit the eggs upon hatching but rather burst or break through the shells" (William Lamar,

pers. comm.). Frank Groves described eggs and young (1957) and albinism (1965) of the Corn Snake (*Pantherophis guttatus*) at the Baltimore Zoo. Lederer (1950) discussed hybridization in ratsnakes. Barnard et al. (1979) from Zoo Atlanta followed growth and food consumption in the Corn Snake. Orangutans and gorillas are afraid of Black Ratsnakes (Murphy et al. 2014, Fig. 12). Clarke (1973) recorded longevity in a Great Plains Ratsnake (*Pantherophis guttatus emoryi*). Dowling (1959a) noted egg-eating adaptations in the Chinese Ratsnake, *Elaphe carinata*. During the 1970s, political relationships with China were tense so virtually no herpetofauna from the region was being imported into the US. When relations improved, a few reptile dealers began to bring in some ratsnakes such as *Elaphe dione, E. schrenckii, E. carinata, E. bimaculata,* and *Orthriophis moellendorffi*. Some of these were sent to zoos but after a few weeks, there was unacceptable mortality. Upon necropsy, it was discovered that gall bladders had been removed for the medicinal market and the surgical site stitched so expertly that it was virtually impossible to notice. Two references on ratsnakes are especially helpful: Schulz 1996 and Rhodes 2008.
